Linking Gut Dysbiosis and Neuroinflammation Observed in Individuals with Autism Spectrum Disorder and Possible Treatment with Bacteroides Fragilis

Abstract
Autism spectrum disorder (ASD) is a term that encompasses neurodevelopmental disorders characterized by behavioural, communication, and social deficits. In addition to this triad of impairments, changes related to cellular processes including gut permeability, neuro anatomical alterations and neuroinflammation have also been identified in individuals with ASD. Patients with ASD also demonstrate altered proportions of bacteria in the gut. Since the gut microbiome has a significant impact on many physiological processes including those beyond the gut, dysbiosis observed in ASD has been the subject of recent research investigating its implications in the aforementioned pathways. This review will explore the specific cellular processes drawn from this research. The specific dysbiosis observed in ASD will be defined and linkages will be drawn to relate bacterial processes to the aberrant cell processes in ASD. Microbiota-related treatments will also be outlined based on the current understanding of the dysbiosis-ASD relationship. Finally, the evidence reviewed here will outline areas of ambiguity and provide a foundation for further research into specific pathways.

Keywords: Autism spectrum disorder; Gut permeability; dysbiosis; Neuroinflammation

Introduction
Autism Spectrum Disorder (ASD) is a range of neurodevelopmental disorders that demonstrate the triad of impairments: difficulties in social and emotional understanding, difficulties in communication, and repetitive, stereotyped behaviours and/or interests [1]. As a diagnostic term, ASD has in the fifth edition of the Diagnostic and Statistical Manual (DSM5) replaced what DSM-IV classified as Pervasive Developmental Disorders (PDDs), a group of disorders that encompassed five defined disorders: Asperger’s disorder, Autistic disorder, Rett’s Disorder, Childhood Degenerative Disorder, and Pervasive Developmental Disorder Not Otherwise Specified [1]. Each of the PDDs display different behavioural, motor, or intellectual abnormalities but are nonetheless centered around the triad of impairments. Current understanding attributes ASD to the influence of both genetic and environmental factors, where genetic predisposition is highly affected by external variables such as epigenetics [2].

ASD manifests itself as a wide range of symptoms. Patients with ASD not only display the classic triad of impairments, but may also present psychological abnormalities such as attention deficits, sensory hyper- and/or hypo-sensitivities, and behaviours that may be aggressive or self-harming in nature [3,4]. Patients with ASD may have a higher prevalence of seizures, insomnia, and ear infections [3]. Notably, an increased prevalence of GI symptoms such as constipation, diarrhoea, bloating, abdominal pain, reflux, vomiting, and flatulence are also characteristic of ASD [5].

The pathophysiological factors that have been associated with ASD symptoms include structural brain differences, chronic neuroinflammation, oxidative stress, mitochondrial dysfunction, and gut permeability [6-13]. Many studies have demonstrated that brain regions associated with functions that are impaired in ASD have altered activation, reduced or altered connectivity, and distinct integration between different brain areas [14,15]. Additionally, several biomarkers and endo-phenotypes have been associated with ASD such as biomarkers for oxidative damage, blood cytokine levels, and metabolites of mitochondrial functions [16,17]. However, it is important to note that the external validity of many studies is limited by small sample sizes, reproducibility challenges and the heterogeneity of genetic pathways to ASD.

Studies show that over 70% of ASD patients currently experience or have a history of gastrointestinal (GI) complications, suggesting a link between ASD and gut abnormalities [18]. Patients with ASD often have altered microbial compositions, such as increased Clostridium (p=0.0393), Desulfovibrio (p=0.011), and Bacteroides...

nervous system [44,45]. Although there is conflicting evidence fluid where they then directly interact with cells of the central faulty intestinal barrier allows neuro active food derivatives or repetitive actions and social disengagement [43]. Noting the symptoms comparable to those in children with ASD, namely, with endorphin, a type of opioid hormone [41,42]. Prolonged exorphins due to their structural and functional similarities individual [36,40].

extra-intestinal inflammatory disorders can arise when the immune responses and tolerance [36,39]. Both intestinal and tissue [36-38]. It is therefore necessary to the regulation of transportation of macromolecules from the lumen into intestinal antigens. This destabilization of the luminal epithelium is how bacterial products may enter systemic circulation and pass through the blood-brain barrier to alter neurobiology. Specifically, we will be discussing how heightened gut permeability and neuro immune dysregulation may be implicated in the etiology of ASD, as well as the viability of probiotic treatment.

Gut Permeability

ASD is comorbid with many gastrointestinal complications involving increased gut permeability [24-27]. The physical integrity of the luminal barrier is often assessed through the sugar permeability test, which involves simultaneous oral delivery of the saccharides lactulose and mannitol, followed by measuring the urinary lactulose:mannitol ratio [28,29]. Unlike mannitol, lactulose is too bulky to traverse the luminal mucosa via aqueous pores of the intestinal epithelium [30,31]. For serum lactulose molecules to arise, lactulose must travel in between epithelial cells at areas of cell extrusion [30,32]. Through the sugar permeability test, D'Eufemia et al. [24] reported a significantly elevated urinary lactulose:mannitol ratio in 43% of patients with ASD [24]. Increased serum lactulose suggests the presence of leaky tight junctions linking together adjacent intestinal epithelial cells [24,32,33]. This destabilization of the luminal epithelium allows entry of certain food antigens that induce ASD-related antigenic responses [34] and neurological dysfunction [35]. The propagation of the immune response further damages the mucosa through zonulin-mediated positive feedback [36,37].

Zonulin modulates intercellular tight junctions involved in transportation of macromolecules from the lumen into intestinal tissue [36-38]. It is therefore necessary to the regulation of immune responses and tolerance [36,39]. Both intestinal and extra-intestinal inflammatory disorders can arise when the zonulin pathway is deregulated in genetically susceptible individuals [36,40].

Food-derived opioid-like peptides can be referred to as exorphins due to their structural and functional similarities with endorphin, a type of opioid hormone [41,42]. Prolonged opiate exposure in animal models is shown to yield behavioural symptoms comparable to those in children with ASD, namely, repetitive actions and social disengagement [43]. Noting the implications of diet on schizophrenia, studies speculated that a faulty intestinal barrier allows neuro active food derivatives or exorphins to travel into the blood and later the cerebrospinal fluid where they then directly interact with cells of the central nervous system [44,45]. Although there is conflicting evidence concerning whether endogenous endorphins are elevated in autism. In addition to entry of incompletely digested foods, increased gut permeability has also allowed the increased levels of serum pathogenic compounds arising from gut dysbiosis [46,47]. Specifically, we will be examining propionic acid, a short-chain fatty acid produced during bacterial fermentation, as well as the release of lipopolysaccharides from the membrane of gram-negative bacteria. Through blood circulation, these compounds are able to travel from the gut lumen to the CNS where they interfere with cellular respiration, microglia regulation, and other pathways that may be related to the neurobiology of ASD [48,49].

Maternal Immune Activation (MIA) Murine models and Bacteroides fragilis Treatment

Experiments on mice have shown that infections leading to maternal immune abnormalities during pregnancy can lead to symptoms equivalent to those seen in ASD, providing further evidence that some environmental factors altering maternal and fetal immune systems may lead to fetal predisposition to ASD [50,51]. Applying the findings from observational studies on human ASD, an ASD murine model was constructed through maternal immune activation, where pregnant mice were injected with immune-activating polyinosinic:polycytidylic acid (poly I:C) to produce offspring that served as phenotypic models of ASD [52-54]. Offspring of MIA mice exhibit ASD-like pathologies and symptoms, such as defects in intestinal integrity, alterations in the microbiome composition, intestinal cytokine levels and metabolome profiles analogous to that subsets in the human ASD population [54,55]. Symptomatic similarities between human ASD and MIA offspring suggest that the MIA offspring serve as reliable models of ASD. Most of ASD-associated behavioural and metabolic symptoms in these mice were ameliorated through oral treatment of Bacteroides fragilis, a bacterial species shown effective against colitis [52]. MIA-induced microbiome had mild elevations in Clostridia and Bacteroides populations [55]. In the same study researchers noted that although there was insignificant difference in the relative abundance of Clostridia (p=0.8340) and Bacteroidia (p=0.9943) between MIA offspring and controls, the microbial species that experienced slightly greater proliferation within the MIA offspring than within the controls belonged to one of the two classes. The altered microbiome in ASD model mice aligns with studies reporting elevated Clostridium levels in the fecal matter of ASD individuals [56-58]. The exception to the increase in certain Bacteroides (12.02±1.62% control, 13.48±0.75% MIA) and Clostridium (1.00±0.25% control, 1.58±0.34% MIA) species was B. fragilis, which was notably decreased in MIA offspring [52]. Supplementation of B. fragilis back into the intestinal environment of MIA offspring modified the microbiome composition such that it was comparable to that of the controls [52]. There was however no significant effect on the overall gut microbial abundance or diversity (microbiome density p=0.2980, species diversity p=0.5440) upon B. fragilis treatment [52].

Administration of B. fragilis also normalized colonic elevation of IL-6 in MIA offspring [59]. IL-6 is critical cytokine involved in MIA pathways linked to abnormal fetal brain development and predisposition of offspring to neuro developmental pathologies.

Spectrum Disorder and Possible Treatment with Bacteroides Fragilis. J Bacteriol Mycol Open Access 2(3): 00028. DOI:

Interestingly, many ASD symptoms were normalized in MIA offspring upon treatment with B. fragilis. Further research is required to better establish the specific changes in individuals with ASD that are related to gut permeability and neuro-inflammation, as well as the mechanisms underlying the interplay between these changes and microbiota. The relationship between gut dysbiosis and ASD is a field where there are currently a greater number of questions than answers: there is a need for studies with larger sample sizes and better methods for testing gut dysbiosis in individuals. As treatments targeting gut dysbiosis and microbiota-associated pathways are being explored as an avenue ASD treatment, this field still provides a worthwhile basis for further exploration.

Conclusion and Perspectives

Many studies have proposed links between the etiology of ASD symptoms and gut dysbiosis. Given the high prevalence of increased gut permeability in ASD patients, it is hypothesized that poor luminal integrity is an avenue by which bacterial compounds access the central nervous system impair neuronal function. Changes in gut microbiota may result in response to oxidative stress, but also further propagate it. Chronic neuroinflammation, which characterized by neuroglial activation and altered profiles of cytokines, chemokines, and growth factors, is also observed in individuals with ASD. The association between gut flora and neuronal development disorders is further supported by a maternal immune activation study where phenotypic models of ASD displayed decreased colonies of B. fragilis. Interestingly, many ASD symptoms were normalized in MIA offspring upon recovery of B. fragilis levels through oral administration. These findings demonstrate that alterations in the gut microbiome can contribute to the development of ASD-associated symptoms.

An examination of all the evidence presented in this review shows a probable link between gut dysbiosis and ASD; however, the nature of this link should be explored in more depth. Further research is required to better establish the specific changes in individuals with ASD that are related to gut permeability and neuro-inflammation, as well as the mechanisms underlying the interplay between these changes and microbiota. The relationship between gut dysbiosis and ASD is a field where there are currently a greater number of questions than answers: there is a need for studies with larger sample sizes and better methods for testing gut dysbiosis in individuals. As treatments targeting gut dysbiosis and microbiota-associated pathways are being explored as an avenue ASD treatment, this field still provides a worthwhile basis for further exploration.
