Abstract
Foreign body (FB) aspiration is an extremely serious problem in childhood with varied clinical presentation demanding high degree of suspicion on the part of clinician. Here we discuss a case of 3 year old child who aspirated a sharpener blade accidentally while playing and was managed by bronchoscopy. Sharp and pointed foreign bodies in bronchus can result in potentially fatal complications. That can be removed safely by rigid bronchoscopy avoiding open surgical methods. There is only one and similar case reported in the literature previously as migratory foreign body bronchus with our best knowledge.

Keywords: Foreign body; Sharpener blade; Bronchus; Rigid bronchoscopy

Introduction
Accidental inhalation of both organic and non-organic foreign bodies continues to be a cause of childhood morbidity and mortality [1]. The most common foreign bodies in children are coins, but marbles, button, batteries, safety pin and bottle tops have also been reported. While in adults, the most common foreign bodies are bones, dentures and metallic wires [2]. Foreign bodies perforating the trachea ordinarily results in surgical emphysema or respiratory distress and tracheo-esophageal fistula have been reported in literature [3].

Case Report
A 3-year-old male child was referred to our institute with a history suggestive of sharpener blade aspiration accidentally before 3 hours while playing. There was no history of vomiting, respiratory distress or any bleeding from mouth. On examination, vitals were stable and the child was breathing normally with no respiratory distress or cyanosis. On chest auscultation air entry on the left side was lessen as compared to the right side with added sounds (stridor or wheeze). On basis of history and physical examination foreign body aspiration was suspected and a chest x-ray posterior-anterior view was done, which illustrate a radio-opaque rectangular foreign body in the region of the left main bronchus (Figure 1).

Rigid bronchoscopy was performed which revealed a piece of a sharpener blade in the left main bronchus which was impacted within the lumen and not completely blocking the distal airways. FB was grasped with a forceps and removed along with bronchoscope. It was rusted sharpener blade piece measuring size of 1.1 cm x 0.6 cm x 0.1 cm (Figure 2). After removal of the foreign body, the bronchoscope was reintroduced looking for any airway mucosal injury which concealed no abnormality. The post-operative period was uneventful. A chest X-ray was taken at 6-8 hours post bronchoscopy to exclude the presence of pneumothorax or mediastinal emphysema and patient was discharged next day.

Discussion
The diagnosis and treatment of a child with a foreign body in the respiratory tract is a complex process, which necessitate close cooperation of a pediatric, a pulmonologist and a surgical team. The natural urge to explore the objects by mouth, lack of molar teeth, crying and playing while eating and lack of parental
supervision contributes to this hazard in this age group [4]. Adults may swallow non-food objects accidentally or deliberately, when an underlying mental illness or a suicidal cause should be ruled out. An adequate positive history is very informative and helpful for diagnosis, but a negative history is present in about 15% of cases of foreign body aspiration. In the absence of positive history, a good clinical suspicion, physical examination, and chest x-ray could make it possible to diagnose the case [1].

A foreign body aspirated into the air passage can lodge in the larynx, trachea, or bronchi. Of these cases, 80% to 90% are found in the bronchi because their size and configuration allow passage through the larynx and trachea. Larger objects happen to impacted in the larynx or trachea, at times causing complete obstruction which is an acute emergency. In adults, bronchial foreign bodies tend to get lodged in the right main bronchus because of its lesser angle of convergence compared with the left bronchus and because of the location of the carina left of the midline. Because the angles made by the main stem bronchi with the trachea are identical until age 15 years, foreign bodies are found on either side with equal frequency in patients in this age group (< 15 years) [5].

The main symptoms associated with aspiration are suffocation, cough, statorax, excessive sputum production, cyanosis or difficulty in breathing. These symptoms develop immediately after the aspiration [6]. Management of inhaled foreign body depends on the type of foreign body and the site of impaction. Laryngeal and aspiration [6]. Management of inhaled foreign body depends on the type and location of the foreign body [9].

For multiple pointed objects or objects with sharp cutting edges, a large diameter rigid bronchoscope can be used to protect the mucosa. No such protection is possible with the flexible endoscope [9]. There is a significant risk of bronchial and tracheal laceration and perforation during extraction of such a foreign body with a flexible endoscope. It is a good tool for diagnosing laceration and perforation during extraction of such a foreign body [9].

Conclusion

Foreign body in pediatric airway is a potentially life threatening situation, which requires emergency endoscopic removal. Foreign bodies in the airway continue to be a diagnostic and therapeutic challenge for the practicing otolaryngologist. Because a foreign body can mimic other conditions, particularly without a witnessed event, there can be a delay in management that may leads to complications. Sharp and pointed foreign bodies in bronchi can result in potentially fatal complications. Also, sharpen foreign body may migrate from one main bronchus to other and produce respiratory obstruction of the previously normally ventilating lung. So, it should be considered as early as possible, requiring immediate treatment [8].

The technique of anesthesia for foreign body removal in children is influenced by the general condition of the patient, the preference and experience of the anesthesiologist and the surgeon, and the type and location of the foreign body [9].

After the bronchoscopy, the child should be observed in an anesthesia recovery room for stridor, respiratory distress or other signs suggestive of subglottic edema, damaged teeth, hemorrhage, broncho-spasm and airway perforation. A chest radiograph should be obtained following bronchoscopy to exclude the presence of pneumothorax or mediastinal emphysema.

prompt recognition and early treatment to minimize the potentially serious and sometimes fatal consequences. However, the most effective treatment of foreign body accidents is their prevention.
