Solid pseudopapillary neoplasm of the pancreas: report of two pediatric cases

Abstract

Solid pseudopapillary neoplasm of the pancreas (SPNP) is a rare malign tumor found in childhood. It is more frequent in young women on the second or third decade of their lives. Clinical features go from asymptomatic, abdominal pain, palpable mass, nausea, vomiting and jaundice to pancreatitis. Although the tumor is diagnosed in its necrotic phase this malignant exocrine tumor has a good prognosis after its excision. We report 2 patients who presented a SPNP at 6 and 9 y/o, one of them male (even rarer within the SPNP). In one of the two patients (Case 2) tumor histopathology study was found on his first phase. So, SPNP should be ruled every time we find an abdominal mass in children.

Case presentations

Case 1

A 6 y/o female presents with a 2 months history of left upper quadrant pain, early satiety, post prandial nausea and occasional vomits. No remarkable signs were found on physical examination (PE). An abdominal ultrasound (US) revealed a retroperitoneal mass. Laboratory tests showed CA 19-9, alpha fetoprotein (AFP) and carcinoembryonic antigen (CEA) on normal range. A spiral scan CT (SSCT) (Figure 1) disclosed a hypodense cystic lesion with peripheral contrast enhancement of 5.8x4.9cm placed on the pancreas tail displacing spleen, left kidney and stomach. The tumor was surgically removed by laparoscopy and anatomopathology (AP) revealed a 7.5x6.0x4.0 cm tumor (Figure 2) with a 60% black-purplish necrotic area surrounded by white viable pancreatic tissue. Microscopy confirmed a SPNP (Figure 2). Immunohistochemistry (IHC) showed neoplastic cell positive to cycline D1, CD-99 paranuclear dot (Figure 2), vimentin, Ki-67 < 1%, weak progesterone receptor; and, negative E-cadherin, CD-56, estrogen receptor and CD-34. The patient was discharged on the tenth day post-surgery and received a 12 months close follow up without evidence of recurrence.

Abbreviations: SPNP, Solid pseudopapillary neoplasm of the pancreas; CT, computed tomography; PE, physical examination; AFP, alpha fetoprotein; CEA, carcinoembryonic antigen; SSCT, spiral scan CT; AP, anatomopathology; IHC, Immunohistochemistry; MRI, magnetic resonance imaging; NSE, neuron specific enolase

Introduction

Solid pseudopapillary neoplasm of the pancreas (SPNP) is a rare exocrine tumor, which represents between 0.1-2.8% of all pancreatic tumors. First described by Frantz in 1959, SPNP commonly presents on young women around the second and third decades of life. It is a low grade malignant tumor, with a 5 year survival rate of up to 100%. The tumor can be asymptomatic. Diagnose can be done with a computed tomography (CT) and is confirmed by biopsy. The curative treatment is the complete resection of the tumor.

Case 2

A 9 y/o male presents with a 3 months history of right upper quadrant pain, palpable mass, jaundice and weight loss. Blood tests showed an increase of CA 19-9, alpha fetoprotein (AFP) and carcinoembryonic antigen (CEA) significantly above normal range. A spiral scan CT (SSCT) (Figure 1) showed a hypodense cystic lesion with peripheral contrast enhancement of 7.5x6.0x4.0cm placed on the pancreas tail displacing right kidney and stomach. The tumor was surgically removed by laparoscopy and anatomopathology (AP) revealed a 7.5x6.0x4.0 cm tumor with a 90% yellow-black necrotic area surrounded by white viable pancreatic tissue. Microscopy confirmed a SPNP (Figure 2). Immunohistochemistry (IHC) showed neoplastic cell positive to cycline D1, CD-99 paranuclear dot (Figure 2), vimentin, Ki-67 < 1%, weak progesterone receptor; and, negative E-cadherin, CD-56, estrogen receptor and CD-34. The patient was discharged on the tenth day post-surgery and received a 12 months close follow up without evidence of recurrence.

Case 2

A 9 y/o male, with history of appendectomy and peritonitis, Meckel diverticulum’s surgery 6 years ago and chronic constipation came to the hospital complaining of 1 year of mild to moderate colic epigastric intermittent pain. Two months before admission he had abdominal distension, intermittent vomits and sporadic headache. His primary care physician ordered an abdominal US which showed a 2.5x1.9 cm hypoechoic ovoid lesion; later, the SSCT and Magnetic resonance imaging (MRI) revealed a 2.1x1.6x1.8 cm tumor on the pancreas body (Figure 3). Tumor markers CA 19-9 (Normal: < 37U/mL) and AFP were normal. An Endoscopic Ultrasound (EUS) biopsy showed only adipose tissue. A distal pancreatectomy of the neck, body and tail was performed. AP revealed a 1.7x1.4x1.2 cm tumor lesion on the tail of the pancreas. Microscopy showed solid and pseudopapillary patterns on tumor cells (Figure 4). On IHC tumor cells were positive for cycline D1 (Figure 4), progesterone receptors, Ki-67 < 2% and negative for pan cytokeratin, CD-99, estrogen receptors, chromogranin, synaptophysin and not representative vimentin. The patient was discharged at 10 days post-surgery.

Clinical presentation can range from asymptomatic to abdominal pain, nausea, vomiting, jaundice, pancreatitis or palpable mass. It can be located on any part of the pancreas but usually present on tail, then around the head and neck. Diagnosis should be suspected on any mass inside the pancreas and ultrasound detects SPNP of more than 0.5-34.5 cm. Either a CT or MRI can be performed to discover the extension and infiltration of the tumor. Endoscopic ultrasound guided fine needle biopsy of the lesion usually allows the AP identify the solid and pseudo papillary patterns on hematoxylin-eosin stain; and in some cases hemorrhagic, necrotic, or cystic areas can be found. IHC is mandatory to rule out other malignancies. Nonspecific markers for SPNP are: vimentin, CD56, α-1-antitrypsin, neuron specific enolase (NSE), synaptophysin, α-1-antichymotrypsin, fosfolipase A2, e-cadherin, progesterone receptor, α-1 antitrypsin, neuron specific cytofilm and CD10. The combination of these markers is mandatory to rule out other malignancies. CD99, in pancreatic neuroectodermal tumors; CD10, APC/β-catenin, cycline D1, gaelitin-3, e-cadherin, progressterone receptor, α-1 antitrypsin, neuron specific cytofilm. On the other hand tests are negative for: chromogranin A only found in neuroendocrine pancreatic tumors; CD99, in pancreatic neuroectodermal tumors; and finally estrogen receptor and, ki-67, pan cytokeratin are also negative. SPNP may be clinically difficult to differentiate from other pancreatic neoplasms, especially serious microcystic adenoma, mucinous cystic neoplasm, intraductal papillary mucinous neoplasm, neuroendocrine cystic tumors, remaining SPNP the rarest one. Differential diagnosis also includes pancreatic teratoma and pancreatoblastoma; but when calcifications and an abdominal palpable mass are present SPNP must be suspected. Treatment involves the complete extraction of the tumor through a laparotomy or laparoscopy. Distal pancreatectomy, Whipple or Langmire procedures are the usual approaches. Metastases are rare, but liver, lymph nodes, peritoneum, hepatic portal vein and spleen have been described. In our cases no metastasis were found. Inpatient observation usually lasts around 7 days post-surgery and the prognosis is good in most of the cases. If metastasis is found chemotherapy and radiotherapy can be used allowing a 5 year survival between 6 months and 17 years.

Discussion

SPNP are the slow growing malignant exocrine “borderline” neoplasms with a good prognosis, that represent 1-2% of pancreatic tumors and takes years to doubles its size. SPNP are prevalent in women on the second-third decade of live. Over the years they received several names such as epithelial papillary neoplasm, cystic papillary neoplasm, Frantz tumor, among others, until 1996 when WHO categorized it as SPN. Its etiology is still unknown but may be related to sexual hormones. Its prevalence has been increasing over the years particularly in Asia; they are rare in children especially in males. From 500 cases of SPNP reported in a study only 35 been on children. Another review showed 718 cases of SPNP which 167 were children from Europe, EEUU and Japan. In Peru 629 cases have been reported, mostly of adult women. In this report we present two cases uncommon pediatric cases, a 6 y/o female and a 9 y/o male.

Conclusion

In spite of its rarity, when a pancreatic mass is found in children, the differential diagnosis should include SPN of the pancreas. Diagnosis can be challenging but technologic advances such as EUS can be helpful. Prognosis after complete resection is good.
