The Significance of Diagnostic Delay in Endometriosis

Editorial

Endometriosis is a common gynecological disorder, which affects 5-15% of women of reproductive age, with a varied prevalence [1] depending on the population in question and the presence of infertility [2] and an unpredictable rate of progression [3]. Endometriosis has a chronic nature which often leads to deterioration in quality of life and high psychological morbidity [4-5]. Epidemiological studies highlight a high prevalence of chronic pelvic pain in community care settings, with almost half of these women diagnosed as having endometriosis [6].

The gold standard for diagnosis of endometriosis is surgery, which is advocated as a second line investigation after failure of therapeutic intervention for the management of chronic pelvic pain [7]. Despite progress, the diagnosis of endometriosis remains a clinical challenge with many patients left undiagnosed with an estimated average delay of up to 10.4 years [5,8-10]. Two thirds of women with endometriosis are initially misdiagnosed and almost half are examined by five physicians or more before a correct diagnosis is made [11]. Diagnostic delay is significantly longer in women presenting with pelvic pain in comparison to those presenting with infertility [5,12,13]. In addition, delay before surgical diagnosis of deep infiltrating endometriosis is significantly longer for patients with advanced stage IV disease than for those with stage I, II or III disease [14]. The endometriosis-associated costs to society are aggravated by delayed diagnosis and empirical treatments, as are the costs to the individual when disease symptoms interfere with daily function [5,15,16].

Diagnostic delay in endometriosis is normally considered as the time interval between the appearance of symptoms and the performance of diagnostic surgery. Recently Nnoaham et al. [5] described a delay of 6.7 years in affected women, which was mainly due to delays in referral from the primary care physician to the gynecologist, with women reporting an average of seven visits before specialist referral. Ballard et al. [17] investigated possible reasons for the diagnostic delay in endometriosis using a qualitative questionnaire given to women attending a pelvic pain clinic [17]. The authors found that delays in the diagnosis of endometriosis occur at both an individual patient level and at a medical healthcare system level. At an individual level; women bore symptoms due to inaccurate perception of normal versus abnormal pain, embarrassment, endurance and individual coping strategies; while general practitioners and family doctors tend to normalize symptoms, symptoms are intermittently suppressed through hormones and nondiscriminatory investigations such as a normal transvaginal scan are relied upon. They highlighted the importance of an early diagnosis for women who suffer at physical, emotional, and social levels when they remain undiagnosed. Other possible reasons for this delay may be related to a lack of awareness or knowledge, or simply lack of confidence in surgery results. Early diagnosis of endometriosis refers, by definition, to early surgery, since surgery is the gold standard for diagnosis. But early surgery is not advocated for all patients. In certain cases, empirical treatment is strongly recommended.

Laparoscopic surgery under general anesthesia is most commonly required to reach a definitive diagnosis of endometriosis, but this is expensive and potentially associated with complications [18].

Numerous reasons have been advocated in an attempt to explain the diagnostic delay of endometriosis. Traditionally these could be divided into three groups:

a. Disease related factors, such as overlapping of endometriosis symptoms with other morbidities (i.e., urinary tract infection, interstitial cystitis, pelvic inflammatory disease and others), and the lack of good nonsurgical methods of diagnosing the disease or at least predicting its presence.

b. Patient related factors, including symptom endurance due to inaccurate perception of normal versus abnormal pain, embarrassment, and individual coping strategies.

c. Physician related factors, such as lack of awareness or knowledge, or simply lack of confidence in surgery results.

Although these traditional explanations for the delay in diagnosis may account for a large portion of the delays, I would like to point out some additional factors that may be even more substantial. These have to do with health care medical policy. There is a considerable void in clinical guidelines to direct clinicians regarding the appropriate investigation and appropriate modality, timing and provision of adequate treatment. These could be explained by several factors including:

i. A diversity in symptoms (cysts, pain, infertility or a
combination of these) and in clinical settings (adolescence, chronic pain patients, patients desiring fertility, etc.), has led to lack of guidelines.

ii. Many of the existing recommendations advocate delaying surgery resulting in a delay in diagnosis.

iii. Due to a shortage in adequately powered randomized controlled trials that aim to answer some of the important clinical questions, good evidence-based recommendations cannot be made.

iv. Some of the existing clinical recommendations are too general at best and contradicting and confusing at times (i.e. Does surgery for ovarian endometrioma improve fertility performance or impair ovarian reserve and which type of patient should it be recommended for?).

In conclusion, many physicians in community practice are still largely unaware of the role of specialized care in the optimal management of endometriosis. It is important to dedicate efforts and resources to research and perform randomized clinical trials that will aid in establishing significant evidence based guidelines in an attempt to minimize the delay in diagnosis of endometriosis.
