A Systematic Overview of Cancer Immunotherapy: An Emerging Therapy

Abstract

Radiation, surgery and chemotherapy constitute the “traditional weapons” to fight cancer. But these treatment strategies aim at killing fast proliferating cancer cells and are often associated with many side-effects due to a lack of specificity resulting in normal cells being destroyed. The consequences of such tools are high morbidity leading to patient discomfort and in some scenarios, even death. Thus, the use of such tools is limited and the approach of targeted delivery systems is being exploited currently. Targeted Immunotherapy represents a potential and innovative means to combat cancer. It has become one of the popular means of anticancer therapies due to relatively fewer toxic effects compared to traditional chemotherapy and thereby offers better patient compliance. Cancer vaccines designed against a specific tumor antigen have been efficiently utilized to trigger immune responses against tumor cells. This review provides sheds light on the history of immunotherapy, brief introduction to the concept of immunotherapy and the different types (active and passive), key players of the immune system involved in the anti-tumor defense activities, concept of “immune-surveillance escape”, role of tumor antigens in the design of cancer vaccines, past and the ongoing research in the field of immunotherapy based cancer vaccines, and lastly the limitations of cancer vaccines.

Keywords: Cancer immunotherapy; Tumor antigen; CD4+ T cells; CD8+ T cells; Dendritic cells (DCs); Passive immunotherapy; Monoclonal antibodies; Cytokines; Active immunotherapy; Cancer vaccine

Abbreviations: ADCC: Antibody Dependent Cell Mediated Cytotoxicity; CDC: Complement Dependent Cytotoxicity; CTL: Cytotoxic T lymphocyte; DC: Dendritic Cell; GM-CSF: Granulocyte-Macrophage Colony Stimulating Factor; HPV: Human Papilloma Virus; HBV: Hepatitis B Virus; IL-2: Interleukin 2; IL-12: Interleukin 12; IFN: Interferon; MHC: Major Histocompatibility Complex; MAB: Monoclonal Antibody; NK: Natural Killer Cell; TCR: T Cell Receptor; TSA: Tumor Specific Antigen; TSA: Tumor Associated Antigen; VLP: Virus Like Particle

Introduction

Cancer is one of the most common fatal diseases afflicting people globally. It is believed that cancer will become the leading cause of death across the US population in the near future, thus increasing the need for novel cancer therapies [1]. Cancer is a complex heterogeneous disease characterized by uncontrolled/unregulated division of cells [2]. Despite tremendous progress in the field of cancer biology, cancer remains one of the most deadly diseases to treat [3]. The genetic and phenotypic complexity of this disease underlies its diversity and resistance to therapeutics. Conventional cancer treatment strategies, including radiation, surgery and chemotherapy, play a significant role in the treatment of primary tumors. However, cancer recurrence due to metastasis remains a significant challenge. The inherent ability of the immune defense system to recognize and destroy cancer cells is believed to hold promise toward the eradication of cancers.

Researchers are therefore aggressively seeking novel ways to exploit immune function for cancer prevention. Recently, the approach of targeted immune-based therapies is being exploited. Moreover, the success of the monoclonal antibody Herceptin (Transtuzumab) has revolutionized this field [4]. Immunotherapy represents a potential and innovative means to combat cancer. Targeted immunotherapy has become one of the popular means of anticancer therapies due to better patient compliance. Because of encouraging results obtained from clinical trials, research aimed towards developing a “cancer vaccine” is being carried out extensively [5]. This mini-review focuses on the history, basic concept, key immune players, the current on-going research, hurdles and future aspects in the field of targeted immunotherapy against cancer.

Immune System

The immune “army” is comprised of immune cells such as the eosinophils, macrophages, natural killer (NK) cells and lymphocytes (T and B cells). Amongst all these players, the T and B lymphocytes primarily mediate specific targeted antitumor response [6]. The CD4+ T cells act as “helper cells” and secrete specific cytokines depending upon their profile either Th1 or Th2. The Th1 CD4+ T cells mainly secrete IFN-γ and IL2. IFN-γ is important for the activation of macrophages and microglial cells and facilitate enhanced phagocytic activity. IL2 also known as the T cell growth factor promotes the differentiation of T cells into...
Cancer Immunotherapy

William B. Coley, considered a pioneer in the field of cancer, introduced the concept of immunotherapy by identifying the potential of immune cells in treating cancers and designed a crude vaccine known as ‘Coley’s Toxin’ consisting of killed bacteria that was administered to cancer patients. The patients presented with fever and chills but complete remission of their cancer in some cases [15,16]. His experiment served as a stepping stone for future cancer immunotherapy [17]. Progress toward advances in cancer immunotherapy however, was not without initial setbacks. A significant hurdle was attributed to the difficulty of in vitro culturing immune cells, particularly lymphocytes in vitro. In 1976, interleukin-2 (IL-2), previously known as the T cell growth factor was cloned and was noted for its ability to support the growth of T lymphocytes ex vivo. Studies thereafter, could examine the role of T lymphocytes against cancer cells, leading to the first characterization of a cancer antigen in 1991 [18].

Based on this and other studies, it became widely accepted that the immune system could detect cancer cells and kill them [19]. Such observations also led to the concept that cancer cells express specific proteins (tumor antigens) on their surface which may be specific or over expressed in cancer cells and may not be found or scarcely expressed in normal cells.

Tumor Antigens

Tumor antigens are primarily characterized as two major types [20]. Tumor Specific Antigens (TSAs) are unique to cancer cells and are not expressed on normal cells. TSAs may arise due to point mutations in genes. They may be unique to an individual or may be expressed in various tumors but not normal tissues. The second major type of tumor-antigens is termed Tumor Associated Antigens (TAAs). TAAs are expressed by both tumor and normal cells. They are not tumor specific and their use may result in autoimmunity against normal tissue expressing that Antigen. Examples include MAGE, GAGE, and NY-ES01 [21].

Despite the ability of our immune system to recognize unique antigens expressed by tumor cells, they also can avoid immune attack by employing several “tricks” termed as “tumor immune escape”. For example, the tumor microenvironment, consisting of masses of tumor cells and surrounding stroma, forms a barrier thus limiting immune cell invasion of the primary tumor. In addition, cancer cells may secrete immunosuppressive substances that may inhibit the immune response [22,23]. Furthermore, the immune system may consider cancer cells as “self” since they are of the same origin expressing very similar antigens. Most noted is the ability to express self-antigen in the context of the Major Histocompatibility Class I (MHC I) complex expressed on the surface of tumor cells that is recognized by host immune cells as a non-threatening signal. Thus, the body’s immune system behaves as if it is “blind” to cancer cells. This phenomenon is known as “tumor tolerance”. There is also a possibility that the tumor cells expressing TSAs or TAAs, with MHC I are down-regulated in their surface expression. Thus, allowing the tumor cell to hide from the immune system by not displaying the antigenic peptide and thus is not recognized by the immune system [24]. Together, these mechanisms of tumor escape make it difficult for the hosts to initiate an optimal anti-tumor immune response. To recognize the full potential of immunotherapy, it will be necessary to develop novel approaches to elevate and/or complement immune-based vaccines.

To this end, the goal of cancer immunotherapy must be:

1) To specifically target cancer cells;
2) To recruit efficient immune cells that can generate a robust and long lasting response; and
3) Most importantly prevent relapse [19].

Types of Cancer Immunotherapy

Cancer immunotherapy may involve passive or active immunotherapy alone or in combination with conventional cancer treatments.

a. Passive Immunotherapy

Passive immunotherapy does not rely on the body’s natural immune system to attack cancer cells but uses components of the immune system such as antibodies which can be made in the laboratory to target tumor antigens [24]. Some examples include Herceptin, Avastin, Rituxan, Campath, Zevalin [21].

Monoclonal Antibodies (mAb) are the most widely used form of targeted cancer immunotherapy in clinic today [25]. mAbs bind to a specific target (antigen) on the tumor cell and their mode of action depends on their ability to engage with growth receptors or with pro-apoptotic targets inducing apoptosis of cancer cells. mAbs also facilitate antigen presentation. As discussed before, DCs are the major APCs of the immune system and play pivotal
A Systematic Overview of Cancer Immunotherapy: An Emerging Therapy

Role of IL-2

IL-2 has demonstrated some encouraging and promising results in many clinical trials [26]. It has been shown to increase production of IFNs [26]. One study has shown that the administration of IL-2 in combination with Herceptin can lead to decreased tumor progression and increased tumor necrosis as compared to treatments given individually. The role of IL-2 in cancer immunotherapy is currently ongoing in the field of cancer vaccines [8]. It is used as an adjuvant therapy and facilitates the immune system of the individual’s immune system receiving the vaccine. Factors affecting the immune system include: age [40], immune suppression due to tumor microenvironment [41], substances secreted by tumor, or immunosuppressive drugs like glucocorticoids, analgesics or anesthetics [42]. Nutritional supplements may enhance the function of immune cells that play a key role in cancer immunotherapy. Previous studies in cancer patients indicate that nutritional supplements improve immune system functioning that may be adversely affected due to existing tumor or surgery [11]. Despite tremendous research that is currently ongoing in the field of cancer vaccines, major hurdles still impede the success of cancer vaccines as listed in (Table 4).

Several new approaches are being investigated, including the use of co-stimulatory molecules, multiple dosing, using combinations of tumor antigens, etc., to overcome the above-mentioned limitations. However, not much effort is being focused on vaccine formulation and delivery routes. The formulation and route of...
delivery of the vaccine is also an important parameter in targeted systems which needs to be addressed soon and would be an integral part in the development of cancer immunotherapy-based interventions.

Table 1: Limitations of monoclonal antibodies (mAb).

<table>
<thead>
<tr>
<th>Limitation</th>
</tr>
</thead>
<tbody>
<tr>
<td>1. Change in expression level of target antigen due to mutations.</td>
</tr>
<tr>
<td>2. Use restricted to a subgroup of patients expressing the unique antigen.</td>
</tr>
<tr>
<td>3. Difficult to get a significant therapeutic response avoiding autoimmunity.</td>
</tr>
<tr>
<td>4. Tumor microenvironment is particularly immunosuppressive limiting mAb success.</td>
</tr>
</tbody>
</table>

A Systematic Overview of Cancer Immunotherapy: An Emerging Therapy

Table 4: Limitations of cancer vaccines.

1. **Variable Antigen expression**: Although a variety of tumor associated antigens have been identified, these antigenic peptides still differ in their ability to generate an effective immune response. Lately, tumor specific antigens have been discovered which further facilitate a tumor specific response, sparing the healthy cells and ruling out the possibility of autoimmunity [4,43].

2. **Low immunogenicity**: Often cancer vaccines are unable to generate a strong immune response. This problem may be solved by incorporation of “immune boosters” such as IL-2 and Granulocyte-macrophage colony stimulating factor (GM-CSF) which act as co-stimulatory molecules and facilitate immune reactions [43].

3. **Tumor microenvironment**: Even if an immune response is generated, the tumor microenvironment may neutralize it. So some strategies must be employed to mitigate the immune suppressive nature of the tumor microenvironment.

4. **Loss of efficacy**: Vaccine may render the desired response initially, but over the time the immune response may diminish which might lead to relapse.

**Figure 1**: Key players of the Immune system.

**Figure 2**: Activation of T cells via APCs.

**Conclusion**

Chemotherapy remains the backbone of cancer therapy. An array of oncogenic signaling pathways have been identified and targeted as points of intervention for cancer therapy. A multitude of inhibitors of such molecular pathways are available commercially or are under clinical investigation [26]. However, in the past decade researchers, immunologists and oncologists have also focused on the role of the immune system to combat cancer via immunotherapy-based cancer vaccines. As stated earlier, like several other conventional therapies, cancer vaccines also have limitations. Several studies have shown the potential of using immunotherapy as an efficient adjuvant treatment modality along with chemotherapy [26]. Thus, the future of cancer therapy lies in a combinatorial approach. Targeted chemotherapy and immunotherapy shows great promise to be the foundation of a new era of cancer therapeutics.
