Enterobacter cloacae inhibits simian rotavirus (SA-11) infectivity in vitro

Abstract
Rotavirus (RV) is a major agent of acute gastroenteritis in human worldwide. Currently no efficient drug to inhibit RV gastroenteritis and vaccines remains the only available strategy to prevent and control RV infections. This study aimed to investigate the effect of Enterobacter cloacae on RV infections in vitro. For this purpose, the cytotoxic effect of this bacterium on cell culture was tested then the antiviral assay was conducted using different concentrations of E. cloacae and strategies to understand the mechanism by which E. cloacae can inhibit RV infections. Our results demonstrated that E. cloacae was safe to cells at concentration up to 1.00E+0 CFU/ml. The highest antiviral activity was observed from E. cloacae at concentration 1.00E+0 CFU/ml when the cell lines were treated with the E. cloacae plus RV together at the same time (competition assay) and when the cell lines treated with E. cloacae before RV infection (pre-treatment assay), protecting 62% and 55% of cell line, respectively, with reduction in virus titers by 1.5 log.TCID50/ml and 1.3 log.TCID50/ml, respectively. Our findings revealed the potential of E. cloacae in inhibition of rotavirus infections.

Keywords: Enterobacter cloacae, rotavirus, gastroenteritis, in vitro

Introduction
Acute diarrhea is a common and important cause of childhood death and mortality in developing countries.1 Gastrointestinal diseases are one of the leading causes of mortality in children less than 5 years of age, accounting for almost 10% of mortality in this age group.2-5

Rotavirus (RV), within the Reoviridae family, is a non-enveloped virus with 11 segments of double-stranded RNA and it is classified into 50 P types and 35 G on the basis of VP4 (protease-sensitive) and VP7 (glycoprotein) protein, respectively. RV represent the most important etiologic agents of viral gastroenteritis in infants and young children, as well as many young animals worldwide.6 It is also the major viral agent of acute gastroenteritis in children<5 years of age, which may lead to death in severe cases.6 The primary route of RV transmission is the fecal-oral route via person-to-person contact or swallowing of fecally contaminated water and food, with waterborne being one of the most important exposure pathways.6-10 Currently no efficient drug inhibit RV infections and vaccines remains the only effective and economical means to control and prevent RV infections.12

It has been documented that human norovirus-like particles interacts with E. cloacae SENG-6 isolated from a stool specimen of a healthy person through extra cellular polymeric substances (EPS) where histoo-blood group antigen (HBGA)-like substances were localized.13 In addition, Amarasiri et al.,14 reported that HBGA-like substances excreted in the EPS of E. cloacae SENG-6 displayed the strain dependent recognition and removal of human norovirus-like particles. Therefore, HBGA positive bacteria-virus system can provide an excellent platform to investigate the contribution of specific interactions on human enteric virus survival and removal. In this study, we studied the effect of E. cloacae on rotavirus infectivity in vitro.

Material and methods
Preparation of bacteria
E. cloacae was activated by three successive transfers in modified MRS followed by three successive transfers in sterile 10% reconstituted skim milk powder and incubated at 37°C. Then plated on MRS media and incubated for 24 hr at 37°C, selected one separate colony in tryptone soy broth to start serial dilution to prepare different bacterial concentrations.

Cell lines and virus
MA104 cell line (African green monkey kidney) was purchased from VACSERA (Holding Company For Biological Products And Vaccines, Egypt) and cultivated in cell culture flasks (75cm2) in minimal essential medium containing Eagle’s salts (MEM) supplemented with 5% fetal bovine serum, 1% antibiotics and antifungal (PSA-penicillin G Cultilab 100U/ml/100 g streptomycin sulfate/mL /Amphotericin B 0.25g/ mL). All chemicals required for cell line growth were purchased from Lonza, Belgium. Simian rotavirus SA-11 stock was pre-activated with trypsin 10 mg/ml trypsin for 30 min at 37°C. The diluted tenfold of activated RV stock was replicated in MA104 cells and the cytopathic effect was checked after 72h of incubation. The 50% tissue culture infectious doses 0.1 ml (TCID50/0.1ml) was estimated as described previously by karber method (karber, 1931), then stored in small aliquots at – 80°C until used.

Cytotoxicity assay
The cytotoxicity of E. cloacae on MA104 cell lines in 96 well plate was conducted using a MTT [3-(4, 5-dimethylthiazol-2yl)-2, 5-diphenyltetrazolium bromide] assay as described previously by Lee at al.19 In summary, MA104 cell lines were cultivated in 96-
well microplates with suspensions of 100μl containing various amounts of bacterium ranging from 1.00E+03 to 5.00E+07 CFU/ml then incubated for 48 h. Untreated control cells were also included. After that, the medium was discarded and replaced by 100μL of fresh culture medium containing MTT reagent in each well. After incubation period at 37°C for 4 h, culture medium containing MTT reagent was discarded and 100μL of dimethylsulfoxide (DMSO) was added to each well. Cell Viability were then measured using a Spectrophotometer reader (Asys Expert Plus microplate reader, UK) at 570 nm. The survival rates of cell survival rate was calculated as the average OD value of bacteria treated cells/ average OD value of cell control. The 50% cytotoxic concentration (CC_{50}) is defined as the bacterial concentration that can decrease 50% of cell viability when compared with cell control. Three non-cytotoxic concentrations of bacterium were used for next bacterium-virus interaction assays.

**Effect of probiotic bacteria on RV infection by MTT assay**

MA 104 cell lines were cultivated in 96-well plate. After incubation at 37°C for 24 h under CO_{2} atmosphere, the culture medium was removed and the bacterium-virus interaction was carried out in four different experimental protocols. Three experimental protocols were conducted to study the effect of bacteria on the host cells while the fourth protocol (virucidal) is to investigate the direct effect of bacteria on the viral particles as mentioned in our previous work. After using the bacterium in the antiviral studies, the non-toxic concentrations was defined where E. cloacae was safe to cells at concentration up to 1.00E+06 CFU/ml. At this concentration, the viability rate of MA 104 cell lines was 100% where no morphological changes were observed on the bacteria-treated cells, when compared with cell control. As shown in Figure 1, the cell viability of the RV infected MA-104 was great at the highest concentration of E. cloacae (1.00E+06 CFU/ml), protecting 55%, 62%, 47%, and 54% of RV infected MA-104 during pre-treatment, competition, post-infection, and virucidal assays, respectively.

**Competition assay**

The pre-activated RV was transferred together with E. cloacae onto the cell monolayers for 1 h at 37°C in a 5% CO_{2} atmosphere. After removal the mixed solution, the cell monolayers were rinsed twice with PBS then incubated with FBS free DMEM with trypsin (1%).

**Post-treatment assay**

E. cloacae was inoculated onto the cell monolayers for 1.5 h at 37°C under 5% CO_{2} atmosphere. After removal the unbounded bacteria, the cell monolayers were rinsed twice and the pre-activated RV was transferred onto the cell monolayers for 1 h at 37°C in a 5% CO_{2} atmosphere. Then the culture medium containing unabsorbed virus was discarded and replaced with PBS free DMEM with trypsin (1%).

**Virucidal assay**

100μl of E. cloacae was incubated for 1 h at 37°C with same volume of pre-activated RV. After that, the cell monolayers were inoculated and incubated with the virus-bacteria mixture. In the four experimental approaches, the virus control (cell culture plus virus suspension) and cell line control (cell culture plus medium) were included. To investigate the inhibitory effects of E. cloacae on viral replication, the percentage of cell viability was determined spectrophotometrically by MTT assay as described by Ren et al., (2011) as follows: Percent viable cells = [(ODa-ODv)/(ODm-ODv)] X100, where ODa is the OD value of bacteria group; ODv is OD value of virus control, and ODm is the OD value of blank control. The results were confirmed by TCID_{50} method as described by Reed and Muench (1938). In brief, one non-toxic concentration of E. cloacae with 10-fold dilution of RV were used to inoculate the cell monolayers in four different ways as described above with MTT method. Quadruplicate wells were used for each concentration of the virus. The difference between the values of virus with bacteria and in absence of bacteria is equal to virus titer reductions.

**Statistical analysis**

To evaluate the possible correlation between viral and bacterial in samples, a Pearson correlation and linear regression test, a two way ANOVA test and a Student’s t test were performed using Graph Pad Prism 5.0 (USA); data were considered statistically significant at a P-value ≤ 0.05.

**Results and discussion**

To determine the effect of E. cloacae on RV infection, MA 104 cell lines were infected with virus before, during, after, and at same time of cell treatment with three non-toxic concentrations of the bacterium to understand the mechanism of bacterium-virus interactions. Before using the bacterium in the antiviral studies, the non-toxic concentrations was defined where E. cloacae was safe to cells at concentration up to 1.00E+06 CFU/ml. At this concentration, the viability rate of MA 104 cell lines was 100% where no morphological changes were observed on the bacteria-treated cells, when compared with cell control. As shown in Figure 1, the cell viability of the RV infected MA-104 was great at the highest concentration of E. cloacae (1.00E+06 CFU/ml), protecting 55%, 62%, 47%, and 54% of RV infected MA-104 during pre-treatment, competition, post-infection, and virucidal assays, respectively.

![Figure 1](image-url) The percentage of cell viability under rotavirus infections with different concentrations of E. cloacae in MA-104 cell lines by MTT assay.

The protection rates decreased to 52%, 48%, 16%, and 34% with decreasing the bacterial concentration to 1.00E+05 CFU/ml during pre-treatment, competition, post-infection, and virucidal assays, respectively. Lowest protection rates were occurred with decreasing the bacterial concentration to 1.00E+04 CFU/ml, recording 9%, 23%, 14%, and 19% during pre-treatment, competition, post-infection, and virucidal assays, respectively. In agreement with MTT results, TCID_{50} results were obtained. At the higher concentration of bacteria (1.00E+06), a reduction in virus titers reached to 1.3, 1.5, 0.8, and 1.1log_{10} TCID_{50}/ml during pre-treatment, competition, post-infection, and virucidal assays, respectively (Figure 2).
Enterobacter cloacae inhibits simian rotavirus (SA-11) infectivity in vitro

The percentage of cell viability under rotavirus infections with different concentrations of E. cloacae in MA-104 cell lines by TCID50 assay.

The reduction rates decreased to 1, 1, 0.3, and 0.6 log_{10} TCID_{50} ml during pre-treatment, post-infection, and virucidal assays, respectively, with decreasing the bacterial concentration (1.00E+05 CFU/ml). The reduction in virus titers at the lowest concentration of bacteria (1.00E+04 CFU/ml) was not significant as 0.2, 0.4, 0.2, and 0.3 log_{10} TCID_{50} ml during pre-treatment, competition, post-infection, and virucidal assays, respectively. To our knowledge, this is the first in vitro study to evaluate the effects of E. cloacae on rotavirus infectivity. However E. cloacae has been reported to inhibit other enteric viruses such as norovirus infectivity in neonatal Gn pigs. There are some reports that HBGA bacteria interact with norovirus and rotavirus, enhancing their replication. However, a clear differences was found between rotavirus strains in their ability to use HBGA as receptors against acute rotaviral infections.

In conclusion, the E. cloacae was able to induce protective effects against acute rotaviral infections in vitro, which might through direct interaction with viral capsid, blocking the virus receptors on the cell surface, and/or interference with the virus life cycle inside the host cells. Further studies in vivo would be conducted to confirm these results.
