A 45-year-old female patient presented with intense low back pain for 2 years, irradiating for both lower limbs and perineum with significant worsening in the orthostatic position. She referred weakness of lower limbs and bladder dysfunction with urinary retention. She developed renal insufficiency with increase of urea nitrogen (73mg/dl) and creatinine (2.5mg/dl). Patient had controlled high blood pressure, without other comorbidities.

**Physical exam**

Patient needed crutches to walk. She presented with hypoesthesia in the plantar region of left foot and degree IV force for plantar flexion of both feet. Anal sphincter reflex was reduced and she had recurrent urinary retention, with intermittent urinary catheterization. No signs of myelopathy or pyramidal release were found.

**Electroneuromyography**:

Chronic axonal loss of low sacral roots.

**Computed tomography**:

Significant bone destruction of posterior elements of S1 and S2 (Figure 1).

Magnetic Resonance Imaging (MRI) showed a perineural cyst extending from S2 to S4, remodeling posterior walls of S2 and S4 and enlarging sacral foramina of S2 to the right and S3 to the left, occupying almost entire vertebral canal (Figure 2).

**Figure 1 CT showed important destruction of posterior elements of A. S1 and B. S2.**

**Figure 2 MRI of sacral spine: giant epidural cyst, from S2 to S4.**

S1 and S2 bilateral foraminal blockage were performed, with significant improvement of pain for 1 week, which then returned.

New MRI, gadolinium enhanced, showed an intramedullary constriction band, at the level of vertebrae S1-S2, with severe stenosis (Figure 3).

We performed wide S2 and S3 laminectomy and foraminotomy and cyst excision. Liquor leakage followed cist incision and nerve fibers were found inside the cyst. We proceeded then raffia of duramater by 6.0 Nyon suture, fibrin glue and muscular plasterer.

Patient presented intense headache post-operatively and, to overcome the CSF leak postoperatively, we used the protocol described by Naves, with seven days with patient at zero degree recumbence. Even so, two weeks after surgery she developed clinical evident liquor leakage, treated successfully by cutaneous excision and skin suture. Since that, she did not have any other complication.
Giant sacral tarlov cyst and renal insufficiency

14–16

Citation: clearance of 38.6 mL/min pre operatively and passed to 60.2 mL/min function. Considering Cockcroft gault formula, she had a creatinine lead to neurogenic bladder, including hemangioma, giant lipomas and creates a reverse flow of urine to kidney and, at advanced cases, external urethral sphincter dysfunction.

Pudendal nerve (somatic efferent commands, S1 to S4) innervates the nerve (pelvic nerve, formed by S2 to S4) contracts the detrusor muscle, the clinical signals described above. Relieve by lying down. Furthermore, these cysts may cause also motor exacerbation by standing, walking, and coughing. Symptoms tend to frequent symptom, in form of persistent back pain or sciatic pain not have histories of trauma, so some authors believe that perineural cyst formation. Four out of the seven patients in Tarlov’s article had a history of trauma.11 Schreiber et al. also supported a traumatic cause of cyst formation.12 Although, many patients with perineural cyst do not have histories of trauma, so some authors believe that perineural cysts are congenital, with a arachnoidal proliferations along the exiting sacral root sleeve.13

Due to cerebrospinal fluid inflow, Tarlov’s cyst can grow, compressing or stretching adjacent nerve roots. Pain is the most frequent symptom, in form of persistent back pain or sciatic pain exacerbated by standing, walking, and coughing. Symptoms tend to relieve by lying down. Furthermore, these cysts may cause also motor deficits and bladder/bowel dysfunction.14 15 Our patient presented all the clinical signals described above.

In physiological conditions, the bladder’s parasympathetic effferent nerve (pelvic nerve, formed by S2 to S4) contracts the detrusor muscle, while sympathetic effferent nerve (T11 to L2) relaxes detrusor muscle. Pudendal nerve (somatic effferent commands, S1 to S4) innervates the external urethral sphincter.17

At filum terminale dysfunction, parasympathetic stimulation is absent, which leads to detrusor weakness that culminates as a neurogenic bladder.18 Concomitantly, dysfunction of S1 to S4 leads to external urethral sphincter dysfunction.17 Chronic neurogenic bladder creates a reverse flow of urine to kidney and, at advanced cases, kidney failure.19

Smith et al.20 described diferents types of sacral tumors that can lead to neurogenic bladder, including hemangioma, giant lipomas and Tarlov’s cyst. At this patient specifically prompt decompression led her to complete recovery of vesical control and partial recovery of kidney function. Considering Cockett gault formula, she had a creatinine clearance of 38.6 mL/min pre operatively and passed to 60.2 mL/min at 6 weeks post operatively.21 It means that she left grade III chronic renal insufficiency (CRI) to grade II CRI with normalization of urea and creatinine blood levels.22

Conclusion

This relate of case corroborates the importance of early decompression of sacral tumors in patients that present with neurogenic bladder dysfunction and consequent renal dysfunction. Early neural decompression can change positively the natural history of the patient, with improvement of the renal function and consequent improvement in the quality of life.
