Determination of shale types using well logs

Abstract

Determination of shale type in shale formation has long been a difficult task. Presence of shales in some of the Iranian reservoir formations are one of the most important subject. Shale types have to be considered, because existence of shale type reduces, effective porosity and permeability of the reservoir to some extent. Allogenic Shale is distributed in formations in three basic types, Dispersed, Laminar and structural. Each of these shale types has different effect on porosity, permeability and water saturation. Dispersed shale type reduces effective porosity and permeability to a great extent, but, laminar and structural have less effect on petrophysical parameters. In this investigation, shale types, Shale volume and effective porosity of shale formations have been determined from well logs based on cross-plotting. In other words, a triangle Density-Neutron cross-plot is used to determine the above parameters. The area of study chosen from central oil fields of Iran, where some of the wells are used (Tabnak Field). Tabnak Well C selected for this study in Kangan Formation, South Pars. This study illustrates that distribution of shale types in Kangan Formation is mainly dispersed shale with few of laminar shale, and the quality of effective porosity ($\phi$) decreases with increasing depth in the Kangan Formation.

Keywords: shaley formation, shale types, cross-plotting, kangan formation, well logs

Introduction

Shale is a fine-grained sedimentary rock usually composed of 50% silt (3.9-62.5μm), 35% clay (0.98-3.9μm) and 15% other fine clastic particles (feldspars, quartz, carbonates, zircon, etc.). Shale is distributed in reservoir formations in three basic types, structural, laminar, dispersed or combination of these three types. Each type of shale is described as given in Ghorab.

Structural shale

Exists in the form of fragments or crystals which are an integral part of the rock framework. In other words, is considered as a portion of rock matrix. This mode of shale distribution has no effect on porosity or permeability.

Laminar shale

Exists as layer of clay minerals within clean formations (i.e. sandstone, carbonate, etc). The effect of this type on porosity and permeability is sometimes severe and should be investigated.

Dispersed shale

Dispersed shale is composed of clay minerals, fragments or crystals which usually found on grain surface, occupying pore spaces between particles. Dispersed shale will include both detritus and diagenetic clay minerals. One or both of these forms may be present in this type shale. This type of shale reduces effective porosity and permeability to a great extent.

Shale affects all well logging measurements to some degree. With using well logging data, presence of shale in a formation can be recognized. Besides, shale types, shale volume and effective porosity can be determined either graphically (Cross-plotting) or analytically using Gamma ray spectrum (CGR).

Methodology

In this investigation, Vsh estimated from cross-plot method is compared with $V_{sh}$ calculated from Gamma ray spectrum (CGR).

Shale volume ($V_{sh}$) calculated from gamma ray spectrum

In this paper, Vsh estimated from cross-plot method is validated with $V_{sh}$ calculated from Gamma ray spectrum (CGR). CGR is the best and most accurate method for determining shale volume. The following equations are used to calculate shale volume.

$$IGR = \frac{CGR_{log} - CGR_{min}}{CGR_{max} - CGR_{min}}, \quad CGR = A\log th + B Log K$$

i. $IGR$ is the Gamma ray index
ii. $CGR_{log}$ is the Gamma ray spectrum in the zone of interest
iii. $CGR_{min}$ is the Gamma ray spectrum in cleanest formation
iv. $CGR_{max}$ is the Gamma ray spectrum in shale zone
v. $A$ and $B$ are Log calibration constants

Then, the shale volume ($V_{sh}$) can be calculated from the Gamma ray index, by the following formula;

$$V_{sh} = 0.33\times 2^{2.8-IGR} \times 1.0$$ for hard formation

$$V_{sh} = 0.083\times 2^{2.7-IGR} \times 1.0$$ for soft formation
V\textsubscript{\text{sh}} = \frac{IGR}{[3-2IGR]} \text{ for gas saturated formation [4]} \quad \ldots \ldots \ldots \ldots (4)

Hydrocarbon correction

More accurate method to correct for hydrocarbon effect on density and neutron porosities before points are plotted on cross-plot are given below:\(^5\)

For the neutron porosity

\[ \Phi_{\text{Ne corr}} = \Phi_N - \Delta \Phi_N \quad \ldots \ldots \ldots \ldots (5) \]

Where

\[ \Delta \Phi_N = \frac{\Phi_N}{(1-0.4 \rho_{h})} \quad \text{for oil} \quad \ldots \ldots \ldots \ldots (6) \]

\[ \Delta \Phi_N = \frac{2 \Phi_N}{(1-0.4 \rho_{h})} \quad \text{for gas} \quad \ldots \ldots \ldots \ldots (7) \]

In fresh mud (less than 50000 ppm) the equation can be reduced to:

\[ \Delta \Phi_N = \left[ (1-0.7 \rho_{h}) + 0.65 \rho_{h} - 0.03 \right] \rho_{m} \quad \ldots \ldots \ldots \ldots (8) \]

\[ \Delta \Phi_N = \left[ 1.11-1.0-0.7 \rho_{h} \right] \rho_{m} \quad \ldots \ldots \ldots \ldots (9) \]

And

\[ \Delta \Phi_N = \left[ 1.07 \Phi_N (\rho_{h} - 0.7) \right] \quad \text{for oil} \quad \ldots \ldots \ldots \ldots (10) \]

\[ \Delta \Phi_N = \left[ 1.11-1.0-1.2 \rho_{h} \right] \quad \text{for gas} \quad \ldots \ldots \ldots \ldots (11) \]

In salinity less than 50000 ppm (fresh mud) the parameter, P can be considered zero. An estimation of hydrocarbon density \( \rho_{h} \) can be obtained by the following equations.

\[
\begin{align*}
\rho_{h} &= \frac{1+0.72}{(1+0.72)} S_{hr} \left( 1-\frac{\phi_{d}}{\phi_{f}} \right) \quad \text{for oil saturated} \quad \ldots \ldots \ldots \ldots (12) \\
\rho_{h} &= \frac{1+0.72}{(1+0.72)} S_{hr} \left( 1-\frac{\phi_{d}}{\phi_{f}} \right) \quad \text{for gas saturated} \quad \ldots \ldots \ldots \ldots (13)
\end{align*}
\]

Residual hydrocarbon saturation is used, because the neutron and density tools investigate the flushed zone. The saturation in the flushed zone is calculated based on the Archie’s equation.

\[
S_{\text{sh}} = \sqrt{\frac{\frac{a}{\phi_{n}} - \frac{R_{mf}}{R_{m}}} {\frac{R_{mf}}{R_{m}}}} \quad \text{and} \quad S_{\text{sh}} = 1 - S_{\text{ms}} \quad \ldots \ldots \ldots \ldots (14)
\]

\( \phi \) is porosity of the formation
\( m \) is cementation factor
\( a \) is lithology constant
\( R_{mf} \) is resistivity of mud filtrate
\( R_{m} \) is resistivity of flushed zone (micro resistivity tool response)

Shale volume (\( V_{\text{sh}} \)) estimated from cross-plot (CP)

Generally, cross-plot is a quick and commodious method for estimation of shale volume and shale types with acceptable accuracy in comparison with other methods, such as core and log analysis.\(^7\)

In this cross-plot three distinct points (F, M, SH) are shown Figure 1. Point F represents fluid or water point, where \( \phi_D = \phi_N = 100\% \). Point M represents matrix point. If density and neutron tools are calibrated in term of the existing matrix, then \( \phi_{Ne, M} = 0 \). Point SH represents shale point. The coordinate of point SH \( \phi_{Ne, SH}, \phi_{D, SH} \) must be determined for shaley portion of well and this coordinate vary from well to well and have to be estimated for each case.\(^8\)

Effective porosity (\( \phi_{e} \)) estimated from cross-plot (CP)

Line M-F represents clean formation or \( V_{\text{sh}} = 0 \) line. This line is scaled in effective porosity as shown in Figure 1. Points representing \( \phi_{Ne, SH} \) and \( \phi_{D, SH} \) values in clean formations will fall on M-F line and their position on the line indicate effective porosity values. Line M-SH represents \( \phi_{e} = 0 \) line and value of each point on this line indicates shale volume of the formation that has no effective porosity. Points that represent shaley formation fall within triangle. Because porosity values do not exceed 50\%, line M-F is plotted till 50\% porosity to make full use of cross-plot.\(^9\) Following equations have been used to construct this triangle.

\[ \phi_{e} = \phi_{Ne, SH} - (\phi_{Ne, SH}, V_{\text{sh}}) \quad \phi_{e} = \phi_{D, SH} - (\phi_{D, SH}, V_{\text{sh}}) \quad \ldots \ldots \ldots \ldots (15) \]
In Figure 1 laminar shale points fall on LAM or around LS-SH line, dispersed shale points fall on or around DIS line and structural shale point’s fall on or around STR line.

For each point within triangle $V_{sh}$ is estimated on M-SH line parallel to clean formation line (diagonal line), and also, $\phi_e$ is determined on clean formation line parallel to M-Sh line. For example point A in Figure 1 represents a shaley formation that has values of $\phi_e = 9\%$ and $V_{sh} = 23\%$. Shale type for this point is dispersed.\(^{11}\)

If formation contains hydrocarbon, Neutron and Density porosities have to be corrected before points are plotted, by using the equations (4-17).

**Determination of shale types in kangan formation**

There are five depths interval selected for this study from Kangan Formation, well-C Figure 2. The results for each interval have been given below.

![Figure 2 Location of well-C in Tabnak field.](Image)

**Depth intervals “2590-2592m”**

This interval of formation has considerable volume of shale and saturated with formation water Figure 3. After plotting measured points of this interval on cross-plot Figure 4 is seen that aggregation of points is around laminar shale line. So, distribution mode of shale for this section of formation is laminar. $V_{sh}$ and $\phi_e$ estimated from cross-plot for each point of this interval are given in Table 1.

![Figure 3 Full set log data for 2590-2592m depth interval.](Image)

**Depth intervals “2650.3-2652”**

This section has no shale and there is gas in formation Figure 5. So, neutron and density porosities must be corrected for hydrocarbon effect. Figures 6, Figure 7 shown positions of points before and after
Correcting hydrocarbon effect for neutron and density porosities on cross-plot and is seen that points fall on clean formation line after hydrocarbon correction. For this interval, $\phi_e$ estimated from cross-plot, corresponds to 15.2 to 16.8% Table 2 and effective porosity measured with core analysis method is 17.1 to 18.2%. As one can be seen, this result is very close together, and therefore, this method can be applied to estimate effective porosity with acceptable accuracy. $V_{sh}$ and $\phi_e$ determined from cross-plot for each point of this interval are given in Table 2.

**Depth intervals “2718.5-2719.5m”**

This interval of formation has intermediate volume of shale and saturated with formation water Figure 8. After plotting measured points of this interval on cross-plot Figure 9 we seen that points occupy the area between laminar and dispersed shale lines. So, distribution mode of shale for this section of formation is combination of laminar and dispersed types. $V_{sh}$ and $\phi_e$ estimated from cross-plot for each point of this interval and are given in Table 3.

### Depth intervals “2718.5-2719.5m”

With comparing $V_{sh}$ estimated from cross-plot method and $V_{sh}$ calculated from gamma ray (with using of CGR) is seen that these values are very close together for each point Figure 10, therefore, cross-plot method can be used to determine shale volume and effective porosity with acceptable accuracy.

Determination of shale types using well logs

Copyright: ©2017 Alaskari et al.

Results and discussion

This investigation is done for many depth intervals of Tabnak Well C in Kangan Formation, central Iranian oil field. By using distribution of shale types for each interval, shale volume and the effective porosity for each point have been estimated by cross-plotting method. A triangle neutron-density porosity cross-plot has been applied for this purpose.

i. For data sets used in this investigation the range of accuracy for determining shale volume using CGR and CP are 89.7% to 99.7%.

ii. This study illustrates distribution of shale types in K-Formation mainly dispersed shale with few of laminar shale.

iii. Based on effective porosity estimated in this investigation, reservoir quality decreases with increasing depth in K-Formation.

V_sh estimated from cross-plot has been validated with V_sh calculated by Gamma ray spectrum using equations (1) and (3) in unsaturated shale and equation (4) in gas saturated shale. Also, \( \phi_e \) estimated using cross-plotting method has been compared with \( \phi_e \) measured by well logs. In shaley formations saturated with hydrocarbon, equations (4) to (17) have been used for correction of shale volume and effective porosity. It is seen that, these shale volumes are very close together. Therefore, cross-plotting method can be used to determine shale volume and effective porosity with acceptable accuracy.

Cross-plotting is a quick and commodious method in comparison with other methods, such as core analysis or well logs for determining petrophysical parameters.

This method can be used for any formation which has shaley layers using cross-plotting of \( \phi_{NSh} \) versus \( \phi_{DSh} \) in each depth interval. Shale types should be determined and recalibrated after a few well has been drilled. The results of this method can be used to estimate productivity and capacity of a reservoir.

Conclusion

a. Cross-plotting method can be used for determination of shale types, shale volume, and effective porosity with acceptable accuracy.

b. In case of structural shale, correction for effective porosity is not necessary, but depends on type of clay minerals in this shale type.

c. In case of Laminated and dispersed types corrections for Vsh and PHIE are essential.

d. In case of gas saturated shale of any type, correction is needed.
