Ketosis (acetonemia) in dairy cattle farms: practical guide based on importance, diagnosis, prevention and treatments

Abstract

Ketosis is an important metabolic disease in dairy cattle which is occurring due to increase of ketone bodies (especially β-hydroxybutyrate) in blood. It is a lactation disorder usually associated with intense milk production and negative energy balance in dairy cattle. Ketosis most times is occurring at the most productive stage of the lactation and makes great financial damages in milk production. In this practical review, incidence and prevalence, etiology, clinical aspects, biochemical findings, diagnosis methods and prevention methods and treatments of ketosis in dairy cattle farms are briefly discussed. Prevalence rate of ketosis is closely related to diet and farm management and also it is identified to be closely related to animal’s genetics. Concentration of serum β-hydroxybutyrate between 1,200-1,400μmol/L is usually threshold for definition of ketosis and clinical (wasting and nervous) and sub-clinical ketosis are two differentially aspects of ketosis in dairy cattle, which are defined according to presence or absence of clinical signs of ketosis in cattle. Prevention of ketosis based on efficient diet, periodic blood, milk and/or urine screening for ketone bodies’ detection, and also body score evaluation in dairy cattle farms are the best methods to early detection of ketosis in animals which can be easily applicable in dairy cattle farms.

Keywords: clinical ketosis, dairy cattle farm, practical guide, sub-clinical ketosis

Introduction

Transition period between late pregnancy and early lactation (also called the periparturient period) certainly is the most interesting stage of the lactation cycle. Classically length of transition period has been defined as the last 3 weeks before parturition to 3 weeks after parturition. Most important infectious diseases and metabolic disorders occur during this time. Ketosis, retained fetal membranes, milk fever, metritis, and displaced abomasums primarily impact cows during the periparturient period. Susceptibility to infectious diseases in this period occurs due to immune suppression during the periparturient period. Ketosis (acetonemia) is an increase of ketone bodies (acetone, acetoacetate, and β-hydroxybutyrate, subsequently referred to as ketones) in blood until they eventually begin to spill over into urine and/or milk. In dairy cows, ketosis is a lactation disorder usually associated with intense milk production and negative energy balance. Ketosis occurs at the most productive stage of the lactation and hence can be extremely costly, as reported by different researchers. Incidence and prevalence

Prevalence rate of ketosis is closely related to diet and farm management and different amounts of prevalence rate have been reported, some researchers reported that it is between 11.1-12.1 percent, but defiant researchers reported that that in some herds in the United Kingdom, up to 33% of cows tested positive for milk or urine ketones, lost weight, and had decreased milk production. Emery et al. reported that about 50% of the cows in some high-producing herds had at least subclinical ketosis and that 20 to 30% of the subclinical cases developed into clinical ketosis. Death due to lactation ketosis is not common. It is identified that prevalence of ketosis is higher in exotic pure/crossbreds than native pure/non-descript. The prevalence is found to be significantly associated with breeds of cattle. There is a high prevalence of ketosis in animals of high genetic potential, as these animals are unable to withstand the pressures arising from the high nutritional demands generated by the production of milk, which ultimately results in development of hypoglycemia that can remain as a challenge to the successful dairy farming business, eventually ruining the life of dairy farmers. It is identified that ketosis and fatty liver syndrome in dairy cattle are closely related to each other and the average annual costs of ketosis and fatty liver syndrome in United States are estimated to be over $60 million.

Definition and etiology

Ketosis is a major metabolic disorder of dairy cows in early lactation, which develops when dairy cows fall into a condition of excessively negative energy balance caused by insufficient dietary intake and generous lactation, and characterized by relatively high concentrations of the ketone bodies acetoacetate, β-hydroxybutyrate (BHBA) and acetone, and a concurrent low concentration of glucose in the blood. A concentration of serum BHBA greater than 1,200-1,400 μmol/L is a common standard used for the diagnosis of ketosis. During early lactation, the requirement for glucose is increased significantly because the production of lactose rises dramatically. Thus, fat mobilization is increased in adipose tissue and more nonesterified fatty acids (NEFAs) are absorbed in the mitochondria of liver cells. Elevated concentrations of NEFA increase lipogenesis and Ketogenesis in hepatocytes. High concentrations of ketone bodies
Ketosis (acetonaemia) in dairy cattle farms: practical guide based on importance, diagnosis, prevention and treatments

Diagnosis

Blood screening: periodic blood screening of herd for BHBA concentration is the easiest way to early detection of ketosis in cattle but plasma BHBA is not a cost effective or convenient analysis for routine analysis and cow side monitoring and the content of acetocetate or BHBA in urine and milk are used for these purposes. Concentrations of BHBA and acetocetate in urine and milk are less than those in blood and the correlation coefficients for blood and milk BHBA and blood and milk acetocetate are 0.66 and 0.62, respectively.17,22 Cow-side tests have the advantage of being inexpensive, giving immediate results, and they can be used as frequently as necessary. A minor source of error is that the concentration of ketone bodies in these fluids will depend not only on the ketone level of the blood but also on the amount of urine excreted or on the milk yield. Milk is less variable, easier to collect and may give fewer false negatives with subclinical ketosis.22 Milk and urine ketone levels have been traditionally detected by the reaction of acetone and acetocetate with sodium nitroprusside and can be interpreted in a semi-quantitative manner based on the intensity of the reaction. Several products are available commercially as test powders or strips are commonly accompanied by a color chart that allows a classification in grades such as negative, trace, small, moderate, large, based on the intensity of the color of the reaction.21 Conventional wisdom is that milk powder tests are not sensitive for detection of subclinical ketosis (report too many false negatives) and urine tests are not sufficiently specific (report too many false positives).21,22 Milk and/or urine screening: the sensitivity and specificity of the nitroprusside powder test with milk in various studies is reported as 28-90% and 96-100%, respectively.23-30 More recently, a milk strip test detecting the presence of BHBA in milk is available and is graded on the concentration of BHBA in μmol/L. In different studies it has reported a sensitivity and specificity of 73-96% and 69-96%, respectively.23-32 These variations are, in part, due to different plasma BHBA reference values (1200 and 1400μmol/L) for designation of subclinical ketosis and different cut points used in urine BHBA. Somatic cell counts greater than 1 million cells/mL will cause an elevation in reading of both the BHBA strip test and the nitroprusside tests.22 A nitroprusside tablet has reported a sensitivity and specificity of 100% and 59%, respectively, compared with serum BHBA concentrations above 1400 μmol/L.16 and a nitroprusside strip test a reported sensitivity and specificity of 78% and 96% with a urine cut point corresponding to ‘small’ on the color chart or 49% and 99% with a urine cut point corresponding to ‘moderate’ on the color chart.21,22 BHBA test strips when used with urine has a reported sensitivity and specificity of 73% and 96%, respectively, at a urine cut point of 100 μmol/L BHBA and 27% and 99% at a urine cut point of 200 μmol/L BHBA.22

Prevention and treatments

Prevention of clinical ketosis is integrally related to the adequate nutrition of the cows, management of body condition, and the use of certain feed additives in the dry and lactating period. Dry matter intake, fiber digestibility, particle size distribution, energy density, fat incorporation in early lactation rations, protein content, feeding systems and rumen size are important subjects which have to be mentioned to preparation of perfect diets in dairy cattle.22 Daily use of sodium propionate (0.25 lb. for each cow) after calving is identified to be preventive against ketosis in dairy cattle farms. Treated cows with sodium propionate not only have higher blood sugar levels and lower blood ketone bodies in their blood, but also have higher

decrease the rates of β-oxidation of fatty acids, gluconeogenesis and the citric acid cycle in hepatocytes. However, contradictory results on the metabolic changes in the liver during ketosis have been reported, with some studies indicating that gluconeogenesis is unchanged in ketogenic situations.12,17-20 The most widespread hypothesis indicates that acetyl-CoA is directed towards incomplete oxidation (Ketogenesis) as a result of low accessibility of oxaloacetate in the mitochondria.21 However, this theory has been criticized, as it is documented that the activity of phosphoeno pyruvate carboxykinase in the mitochondria and cytosol is unchanged in ketogenic situations, and that the gluconeogenic flux is diminished in fasted animals.20 Krebs’ theory which indicates that maintaining a low level of oxaloacetate is the cause of Ketogenesis is probably correct, but the reasoning for it is wrong: the low concentration of oxaloacetate is achieved by a much higher NA DH/ NAD+ ratio in the mitochondria than in the cytoplasm. This should result in a minimal rate of intramitochondrial phosphoenopyruvate formation under ketogenic conditions, accounting for the lower rate of gluconeogenesis during ketogenic periods with inappetence.21 Many researchers have investigated the etiology of ketosis, often leading to contradictory opinions.20,23-25 Briefly, ketosis and/or fatty liver occur when physiologic mechanisms for the adaptation to negative energy balance fail. Failure of hepatic gluconeogenesis to supply adequate glucose for lactation and body needs may be one cause of ketosis; however, poor feedback control of nonesterified fatty acid release from adipose tissue is another likely cause of ketosis and fatty liver. The types of ketosis resulting from these two metabolic lesions may require different therapeutic and prophylactic approaches.26

Clinical aspects and biochemical findings

Clinical and sub-clinical ketosis are two differentially aspects of ketosis in dairy cattle, which are defined according to presence or absence of clinical signs of ketosis in cattle. As mentioned before, concentration of serum BHBA between 1,200-1,400 μmol/L is threshold for definition of ketosis and if mentioned increase of BHBA concentration be occurred with clinical signs it will be named as clinical ketosis and Subclinical ketosis is defined as elevated concentrations of circulating ketone bodies in the absence of clinical signs.14 Two major clinical forms of bovine ketosis are described (wasting and nervous) but these are the two extremes of a range of syndromes in which wasting and nervous signs are present in varying degrees of prominence.22 The wasting form is most common of the two and is manifest with a gradual but moderate decrease in appetite and milk yield over 2-4 days. In herds that feed components separately needs may be one cause of ketosis; however, poor feedback control of nonesterified fatty acid release from adipose tissue is another likely cause of ketosis and fatty liver. The types of ketosis resulting from these two metabolic lesions may require different therapeutic and prophylactic approaches.26
milk production. Oral propylene glycol administration is found to be sharply preventive for ketosis in dairy cattle farms and also to be efficient for make obvious increase in milk production in dairy cattle. Researchers reported that treated cows with 300ml oral propylene glycol daily produced 0.23kg more milk per milking in the first 30 d of lactation, for a total difference of 0.69kg/cow per day. Also propylene glycol -treated cows were 1.50 times more likely to resolve their sub-clinical ketosis and 0.54 times less likely to develop clinical ketosis. These results show the positive effects of oral propylene glycol administration in fresh cows with sub-clinical ketosis by helping to resolve their sub-clinical ketosis and preventing clinical ketosis. In addition, oral propylene glycol improves milk yield during early lactation in cows diagnosed with sub-clinical ketosis. It is identified that propylene glycol most likely reduces fatty acid mobilization from adipose tissue and by this mechanism can be protective against ketosis and fatty liver syndrome. Ruminally-protected choline has preventive effects against imbalanced energy levels in ketosis and/or fatty liver syndrome. It is also identified that choline probably enhances hepatic very low-density lipoproteins secretion. Also shortening or eliminating the dry period is a management strategy that reduces the magnitude of negative energy balance after calving and triglyceride accumulation in the liver and can be protective against metabolic diseases related to imbalanced energy levels like ketosis. It was also reported that prevalence and incidence of subclinical ketosis were significantly reduced (50%) due to monensin-based treatment in dry cows and heifers. The duration of subclinical ketosis for cows that had been treated with monensin was also shorter than others. Monensin treatment significantly reduced the incidence of subclinical ketosis. In addition, monensin significantly reduced the prevalence of positive milk ketone bodies tests. Some of researchers reported that intravenous injection of 500mL of a 50% solution of glucose results in transient hyperglycemia, increased insulin and decreased glucagon secretion, and reduced plasma concentration of non-esterifies fatty acids. It effects a marked improvement in most cows but relapses occur commonly unless repeated treatments are used. Other sugars, especially fructose, either alone or as a mixture of glucose and fructose (invert sugar), and xylitol, have been used in an effort to prolong the response but idiosyncrasies to some preparations, in the form of polypnea, muscle tremor, weakness and collapse, can occur while the injection is being given. To overcome the necessity for repeated injections, propylene glycol can be administered as a drench. The traditional does is 225g twice daily for 2 days, followed by 110g daily for 2 days to cattle, but higher volumes are also used. Propylene glycol (200-700g daily), or salts of propionic acid, can be administered daily for 2 days to cattle, but higher volumes are also used. Propylene glycol is identified as an efficient diet, periodic blood and/or milk or urine screening for ketone bodies detection and body score evaluation in dairy cattle farms are briefly discussed. Prevention of ketosis based on efficient diet, periodic blood and/or milk or urine screening for ketone bodies detection and body score evaluation in dairy cattle farms are the best methods to early detection of ketosis in animals which can be easily applicable in dairy cattle farms.
