Pulmonary blastoma in an adult male

Introduction

Pulmonary blastoma is one of the rare lung tumors and is considered to be distinct from other lung tumors by its pathological features, clinical course and prognosis. Classic pulmonary blastoma is composed of both malignant mesenchymal stroma and epithelial components resembling embryonic lung tissue. Surgery is the standard treatment and the efficacy of adjuvant chemotherapy and radiotherapy has not yet been established.

Case report

Our patient was admitted and managed at Abassia Pulmonary Hospital, Ministry Of Health, Cairo Governorate, Egypt. A 37 year-old Egyptian male presented to our hospital with repeated attacks of blood stained sputum. The first attack dated about 6 months before admission. The patient had progressive shortness of breath over a period of two years. The patient was a smoker of one pack of Cigarettes per day for more than 15 years. There was no significant past history or family history.

Aare admission to the Chest Medicine Department at Abassia Pulmonary Hospital, routine basic investigations were done including complete blood picture with differential count, facing blood sugar and 2 hours ater meal, liver function tests, renal function tests, and coagulason profile. All investigations were within normal. Sputum examinations for AFB for 3 successive days were done and were all negative. Sputum cytology did not show malignant cells.

The P-A view of his chest X-ray showed a well-demarcated right upper and middle lung zones mass. The mass extends to the right lung apex above the inner chest wall and medially extended to the mediastum and the right hilum. The mass has a heterogeneous texture (Figure 1). Chest CT scan (Figure 2) showed a large well defined, heterogeneous right upper lobe mass. The CT showed no significant meditasonal lymph nodes enlargement.

The patient was referred to the Thoracic Surgery Department at our hospital for resecaon of the pulmonary blastoma afer the right upper lung lobe. General anesthesia was conducted via double lumen endotracheal tube for one lung anesthesia. The patient was poisoned in the lateral decubitus posiaon with his right side up. Standard right postero-lateral thoracotomy in the fifth space was done. The tumor mass was seen and felt involving the enare right upper lung lobe and sparing both the middle and lower lung lobes. The mass was well circumscribed, lobulated with firm to hard texture. Classic right upper lobectomy was done. After closure of the bronchial stump with

Preoperaave fiber opaque bronchoscopy showed no endobronchial pathology. Also the broncho-alveolar lavage was negative for both AFB and malignant cells. Preoperaave CT needle guided biopsy revealed a biphasic pulmonary blastoma with both epithelial and mesenchymal components. Preoperaave CT abdomen and bone scinagraphy revealed no evidence of distant metastasis (Figure 3).

The patient was referred to the Thoracic Surgery Department at our hospital for resecaon of the pulmonary blastoma afer the right upper lung lobe. General anesthesia was conducted via double lumen endotracheal tube for one lung anesthesia. The patient was poisoned in the lateral decubitus posiaon with his right side up. Standard right postero-lateral thoracotomy in the fifth space was done. The tumor mass was seen and felt involving the enare right upper lung lobe and sparing both the middle and lower lung lobes. The mass was well circumscribed, lobulated with firm to hard texture. Classic right upper lobectomy was done. After closure of the bronchial stump with
simple interrupted Vicryl 20sutures, the stump was covered using a pedicled intercostal muscle flap as our standard technique in cases of malignancy and TB to guard against postoperative bronchopleural fistula. Postoperative pathology report confirmed the diagnosis of high grade biphasic pulmonary blastoma with free bronchial margin, free pleural issue and negative mediastinal lymph nodes for metastasis (Figure 4). The postoperative course of the patient was uneven. After removal of the satchels; the patient was referred to the Cancer Institute of Cairo University for evaluation and the possibility of post lobectomy chemotherapy and/or radiotherapy (Figure 5).

Discussion

Pulmonary blastoma is a rare primary lung tumor occurring mainly in adults. The incidence is 0.25 to 0.5% of all primary lung tumors. The tumor was first described by Barree and Barnard in 1945, and it was termed by Barnard as “embryoma.” The term “blastoma” was suggested by Spencer in 1961 because the pathogenesis of that tumor was believed to be similar to Wilms’ tumor or nephoblastoma. The World Health Organization (WHO) had classified pulmonary blastomas into three categories according to the histopathology, the first type is pulmonary blastoma which is biphasic, the second type is pleura pulmonary blastoma which is monophasic and occurs commonly in childhood and the third type is the well differentiated fetal adenocarcinoma (WDFA).

The aetiology and predisposing factors are not still fully understood. But, in the literature, there is strong evidence showing the correlation between cigarette smoking and pulmonary blastoma. Our patient was a smoker of one pack per day for more than 15 years. The peak incidence of biphasic pulmonary blastoma is in the fourth decade of life. About 30% of cases occurring in children and the tumor is known as pleura pulmonary blastoma. The age of our patient at the same of present son was 37 years old. Some groups reported a male predominance while others did not. Approximately 60% of patients are symptomatic. Usually biphasic pulmonary blastoma is located in the periphery of the lung, while 25% present with end bronchial tumor. Our patient was a male who complained of bloody sputum and the tumor was proved by pre and postoperative histopathology to be a biphasic peripheral pulmonary blastoma.

The radiological appearance of pulmonary blastoma is usually a solitary pulmonary nodule or a mass with a smooth margin due to the desmoplastic changes surrounding the tumor. Rarely the tumor cavities, calcified or be mulaple. Preoperative aseptic diagnostic procedures e.g. bronchoscopy, mediastinoscopy, CT needle guided biopsy usually cannot diagnose pulmonary blastome due to lack of cellular material and extensive necrosis of the tumor. In our patient CT guided biopsy could diagnose the tumor to be biphasic blastoma and this histopathology was confirmed by the postoperative histopathological examination. The standard treatment of pulmonary blastoma consists of surgical resection. Due to the lack of data, adjuvant therapy with chemotherapy and/or radiotherapy is still controversial. Our patient was referred to Cancer Institute of Cairo university for further evaluation of his need for adjuvant therapy or not. The prognosis of pulmonary blastoma is poor regardless of the histology. The overall 5 years survival was reported to be 16%. Another study the researchers had reported that biphasic pulmonary blastomas have a poorer prognosis than the monophasic well differentiated fetal adenocarcinoma which have a better prognosis and a five years survival around 50%. The factors contribuung to the unfavorable prognosis are the biphasic type, tumor recurrence, metastatic disease on presentation, tumor size more than 5cm, and frequent lymph node involvement.
