Antiphospholipid syndrome in Mexican children: evolution, laboratory and clinical characteristics: a 10-year experience

Introduction

The Antiphospholipid syndrome (APS) is a multisystem and autoimmune disease, which is mainly characterized by the presence of thrombotic events, gestational morbidity, as well as hematological, dermatological and neurological manifestations, in the presence of high titers of Antiphospholipid antibodies. It can present as a primary entity or secondary to another autoimmune disease, mainly systemic lupus erythematosus. After 35 years of its first description, the understanding of this pathology is still evolving and even more in its presentation in the pediatric patients. The presence of Antiphospholipid antibodies has been widely reported in pediatric patients with thrombosis, and less frequently in isolated hematologic and neurological manifestations. APS is considered the most common acquired cause of a prothrombotic state of autoimmune etiology. At the moment, there are no reliable data on the incidence or prevalence of this syndrome in pediatrics. Although the incidence of thrombosis in children is lower than in adults, the thrombosis attributable to Antiphospholipid antibodies is proportionately greater. The long-term morbidity and mortality associated with thrombosis events in pediatric population may be minor or predictable which children are at higher risk of thrombosis, associated to APS, sought to determine prognosis and select patients for prophylactic treatment and more rigorous follow-up.

Objectives

To describe the clinical presentation and evolution in addition to laboratory findings in Mexican pediatric population who developed arterial or venous thrombosis in the presence of high titers of Antiphospholipid antibodies. Retrospective cohort study of the Children’s Hospital of Mexico Federico Gomez, last 10 years.

Method

Retrospective cohort study of the Children’s Hospital of Mexico Federico Gomez, last 10 years. We reviewed the data from the clinical archives of the patients with diagnosis of APS according to the Miyakis criteria, from 2007 to 2017. The variables analyzed include age at diagnosis, sex, subtype of APS, clinical finding of thrombosis, laboratory finding of Antiphospholipid antibodies and outcome.

Results

A total of 29 patients fulfill the diagnosis criteria of APS. The mean age of patients at diagnostic was 9.8 years, with a minor age at diagnosis of 2.2 years and a maximum of 16.4 years of age. Of the total population 52% were females and 48% males. Primary APS was diagnosed in 48%, of which 71% were males. Secondary APS was present in 52% of the population; all diagnosed with Systemic Lupus Erythematosus. Of the patients with secondary APS, 85% were female. Arterial thrombosis was present in 48% of the cases, primarily in the group of secondary APS. Of the total cases 20%

Conclusion

During a 10 year follow up, we diagnosed 29 patients with APS. As reported in literature, a greater percentage of patients are female and present with a secondary APS. Most patients with primary APS are males. In our population, in contrast with what literature report, secondary APS presents with a greater percentage of arterial thrombosis. The mayor site of venous thrombosis was low extremities and of arterial thrombosis were cerebrovascular events. The presence of positive LA implicates a higher risk of thrombosis. Our pediatric population diagnosed with APS requires of a close follow up in order to monitor anticoagulant therapy and to prevent the patients from developing a second thrombotic event that may lead to death.
