Systemic manifestations of ehlers-danlos syndrome hypermobility type

Abstract

Ehlers-Danlos syndrome Hypermobility type is a hereditary connective tissue disease characterized by generalized joint Hypermobility, joint instability, skin changes and musculoskeletal pain. Signs and symptoms of Ehlers-Danlos syndrome Hypermobility type are classified as musculoskeletal or extra skeletal. Pain and fatigue are the most common complaints in the clinical practice. Due to impaired postural structure and biomechanics, associated conditions include nocturnal insomnia and early morning drowsiness, dysautonomia, dyslexia and neuropsychological disorders and illnesses related to impaired restorative phases of sleep. The patient has musculoskeletal pain that affects the activities of daily life and work, as well as shifting the biological clock. It is therefore important to understand the order of appearance and prevalence of signs and symptoms in the general population suggesting a need to investigate the order of these symptoms in population studies.

Keywords: hypermobility, ehlers-danlos hypermobility type, neuropsychological disorders, comorbidities, anxiety, dyslexia, fatigue, pain, collagen

Abbreviations: EDS, ehlers-danlos syndrome; EDS-HT, ehlers-danlos syndrome hypermobility type; JH, joint hypermobility; GJH, generalized joint hypermobility; GI, gastrointestinal

Introduction

Joint Hypermobility (JA) can be the extreme of the range of motion or a condition in a group of hereditary connective tissue disorders. It is influenced by age, gender and ethnicity, has a Gaussian distribution in the physiological range of motion and is considered to be a genetically determined deviation from normality. The JA can be identified in up to 64.6% of the population, including children. Recently a population study was published that identified JA in 41% of Brazilian children. Characterization of this disorder is achieved using the Beighton score. Ehlers-Danlos syndrome (EDS) is a hereditary connective tissue disease caused by genetic alterations related to collagen that produce other health conditions. This syndrome is characterized by generalized JH, joint instability and pain. It has multisystem manifestations and clinical variability affecting the skin, ligaments, joints, blood vessels and internal organs. According to Hamonet et al., a high frequency of EDS is seen in the clinical practice, but the differences of evaluation systems does not allow reliable calculations of its prevalence to be made. EDS is classified by the Villefranche criteria into six subtypes with Ehlers-Danlos Syndrome Hypermobility type (EDS-HT) having the highest prevalence. The phenotypic expression of EDS-HT is variable, even within the same family, making diagnosis a challenge and resulting in under diagnosis of the syndrome. As the terms Joint Hypermobility Syndrome (JHS) and EDS-HT are often used differently in the same classification, the etiology must be confirmed at the molecular level. The signs and symptoms of EDS-HT are classified as musculoskeletal or extra skeletal. Henkel cites a study by Grahame on the main categories of clinical presentation. These symptoms include sagging of musculoskeletal tissue, pain in the joints and in the non-inflamed spine, dislocations, soft tissue injuries and problems with support structures, such as the pelvic floor. Moreover the subject suffers amplification of pain, which can lead to muscle intolerance and deconditioning, and finally, psychosocial sequelae, anxiety, depression, obesity, isolation and anger. All these conditions are often targeted by medical professionals who are unable to help the patient.

The EDS-HT may have systemic manifestations from the mouth to the anus, some of which are benign, and others may be lethal. A thorough knowledge of gastrointestinal (GI) manifestations and their management is mandatory to avoid unnecessary morbidity and mortality. An increased rate of celiac disease was identified in EDS-HT, suggestive of intestinal malabsorption, a possible factor for fatigue. Moreover, individuals have psychiatric disorders and psychosocial impairment, and a high prevalence of anxiety disorders from simple phobias to panic disorders. The EDS-HT is characterized by pain, fatigue, proprioceptive dysfunctions, hemorrhagic syndromes, dysautonomia, dystonia and digestive tract, vesicophrectinal, respiratory, dental, otorhinolaryngological, ophthalmological, gynecological, obstetrical and cognitive disorders, among others. The pains are diffuse and are among the most disabling for fatigue. The EDS-HT suffers amplification of pain, which can lead to muscle intolerance and deconditioning, and finally, psychosocial sequelae, anxiety, depression, obesity, isolation and anger. All these conditions are often targeted by medical professionals who are unable to help the patient.
Discussion and conclusion

The EDS-HT is very common and has systemic manifestations. Pain and fatigue are the most common complaints in the daily clinical practice, followed by nocturnal insomnia and morning drowsiness, dysautonomia, dyslexia and neuropsychological disorders. Furthermore subjects suffer from conditions related to the restorative phases of sleep such as musculoskeletal pain, impaired concentration and cognitive deficits, which are explained, at least in part, by higher organic energy consumption. In this context, there is impairment to activities of daily living, and to the professional and sports life of individuals, a situation that requires an understanding of the order of appearance and prevalence of signs and symptoms in the general population with an emphasis on this diversity of manifestations, a condition that currently suggests analyzes of signs and symptoms based on disturbances of the hyper mobile spectrum.
