Musculoskeletal injuries among adolescent cricketers in Zimbabwe

Abstract

Aim: This is a study to describe and document cricket-related musculoskeletal injuries among high school male cricketers in Zimbabwe during inter-provincial competitions.

Methods: This is a retrospective descriptive study. 240 male cricketers had been taken for this sample. An edited self-reported musculoskeletal questionnaire for pain assessment was used. The questionnaire was designed to obtain musculoskeletal pain, location of injury, type of injury and injury severity. The SPSS version 20.0 statistical software was used for data entry and statistical analysis. Pearson correlation analysis and Chi-square tests were performed. P-value ≤ 0.05 was regarded as significant.

Results: Of the 240 adolescents’ high school cricketers surveyed, 81.25% experienced cricket-related musculoskeletal pain and injury within the previous season. There was a 35% prevalence of injuries among cricket players. The knee, lower back and shoulder were the three common most susceptible anatomical sites of musculoskeletal pain and injuries. Bowlers (36%) and batsmen (32%) had sustained highest percentage of injuries and compared to all-rounders (22%) and wicket-keepers (10%).

Conclusion: Prevalence of musculoskeletal injury/pain is elevated among adolescents’ school boy cricketers. Male cricketers residing in Kwekwe, Zimbabwe experienced a high prevalence of musculoskeletal, ankle, knee, lower back and shoulder pain. Coaches’ conditioning training programs and early rehabilitation by physiotherapists are indispensable to condense the injury rate in high school cricket.

Keywords: all-rounder, batsmen, bowlers, musculoskeletal injury, sprain, strain

Introduction

Many sports have been researched on, for example, soccer basketball and athletics among others due to their popularity in Zimbabwean schools. In African continent, there are few countries playing competitive cricket on One Day International (ODI) and T-test and these are South Africa, Kenya and Zimbabwe. Due that fact not much has been said in school cricket. The uniqueness of cricket is that unlike other target games like archery, darts and shooting; cricket demands hitting a target whilst in motion. This angular motion has a restrictive range of motion which can cause more complicated injuries to the player. Also cricket a more protected target is used despite the complexity of ROM and angular restrictions. Zimbabwe has become more popular in male and female professional cricket and street cricket in the recent decades. This sport is dynamic and involves a scientific knowledge to cope with the new developments in the game. It involves many abstract skills and movements which need to be enhanced so that players are guaranteed that their bodies are kept in shape and strong. At a young age, cricket is for enjoyment, health and professional development. Inevitably, injury is potential outcomes of participation hence young athletes are vulnerable to cartilage which is less resistance to repetitive micro injury, apophysis and growth plate’s injuries. Competitive element intervenes young players’ decreased flexibility due to pronounced growth spurt through training harder and longer times which lead to varied physiologic response to exercise hence injuries.

Bowling, batting and fielding are the three unique aspects of the game of cricket which are associated with risks of injury due to its repetitive nature and played often for long periods of time. In cricket, musculoskeletal pain and injuries are very common. They can occur when a player had rapid rotational movements, collisions with other players, struck by a ball or bat, sliding and diving during fielding and over-use injuries; thus physical macro trauma and microtrauma. A single high force and impact incident results in a macro-trauma which whilst micro-trauma is a result of repetitive or chronic injury which can have a lifetime. Importantly, inadequate nutritional intake, physical training and psychological preparation of players have great effects on muscle strength, endurance, flexibility, agility and fitness in the field of play and therefore hinder player performance in the game of cricket.

Literature concentrate on cricket-related injuries affecting elite fast-bowlers; spinal abnormalities in young fast-bowlers, musculoskeletal pain among adolescent cricketers and prevalence of cricket-related musculoskeletal injuries among elite cricketers mentioning that the most common anatomical sites of injury identified were lower limb, upper limb and lower back whilst limited information exists regarding the Southern Africa high cricketer. It is imperative that the lack of information exists regarding the epidemiology of musculoskeletal pain and injury for high school cricketers. The current study aims at describing and documenting cricket-related musculoskeletal injuries among high school cricketers in Zimbabwe during inter-schools’ competitions.
Materials and methods

Design

The study was a retrospective descriptive study which documented male cricketers’ musculoskeletal pain and injuries in a year’s period. The incidence of injuries documented was during the National Association of School Heads (NASH) U19 cricket championships, which was held in 2015-16 season. Both qualitative and quantitative designs were used. For this purpose, all the teams participating in these competitions were invited to take part in this study.

Sample size and sampling

A total of 252 subjects who volunteered to participate were recruited. In Zimbabwe cricket has been franchised into four main regions; southern, central eastern and northern. This study focus on the central region under auspices of Midwest Rhinos franchise and the paper will not compare injuries sustained in different regions. Only top cricketing schools among the 12 high schools in the region were selected. These players were from five high schools namely; Goldridge, Kwekwe, Mbizo, Shungu, and Rutendo.

Ethical considerations

Ethics approval for this study was obtained from the National University of Science and Technology (NUST) Sports science and coaching department and permission to use the schools were obtained from the Ministry of Primary and Secondary Education, Midlands Province and School Heads. Informed consent was obtained from each of the study subjects and their parents or guardians. Only cricketers with both written assent and consent were used as subjects in this study. The researcher kept subjects’ identity anonymous and confidential.

Data collection

An edited self-reported musculoskeletal questionnaire (combined pain assessment and Borg CR 10 scales) was used. The questionnaire was designed to obtain musculoskeletal pain, location of injury, type of injury and injury severity. At the beginning of the season cricket players were taught how to report pain and injuries. Team medics were used as research assistants to monitor the record of injury from individual players after a match. The information for each injury was obtained throughout the season. A summary of individual player’s seasonal record of injuries was used to complete the questionnaire. Other medical records from other sports played were not obtained since they were not necessary.

Data analysis

The SPSS version 20.0 statistical software was used for data entry and statistical analysis. Pearson correlation analysis and Chi-square tests were performed. P-value ≤ 0.05 was regarded as significant. Hypothesis test was done on the descriptive.

Results

The response rate (240/245) 98%. 5 questionnaires were inappropriately completed hence making them invalid. Anthropometric and demographic characteristics are shown in Table 1. Table 2 shows prevalence of player’s musculoskeletal injury in relation to the players’ role among cricketers. Out of 195 players investigated for pain; 36% were bowlers, 32% were batsmen, 22% of all-rounders, and least were wicket-keepers with10%. The anatomical site for specific musculoskeletlal pain and injury levels on cricket player is shown in Figure 1. Distributions of cricket-related musculoskeletal pain in relation to anatomical sites were; knee (35%), lower back (30%), shoulder (23%), thigh (18%), hands and wrist (16%) and 15% for the neck. Most common injured is the lower limb as compared to the upper limb. Figure 2 shows distribution and extent of each type of injury suffered by high school boys’ cricketers. Most common injuries/pain suffered by cricketers was sprain and strain; however, sprain (45%) was more than strain (30%), wounds were 15%, 5% fractures, dislocation 3% and the least were cramps with 2% (Figure 3).

Hypothesis test was done on the descriptive.

**p< 0.05 values considered significant.
Batsmen and wicket-keepers were subjects who mostly experienced knee pain. This is because batsmen display movements which are either on through forward propulsion or back foot backwards propulsion. These movements mount pressure and tension on the knee and surrounding joints of the patella during flexion and extension, placing the knee joint at increased risk of injury.\(^2\) This is supported by Noorbhai et al.\(^1\) wicket-keepers spent most of the time kneeling down and flexing their knees while playing, which also increases their risk of pain at the knee joint. The findings were in line with literature that the third most common site of injury is shoulder (23%).\(^\text{17}\) This resulted from repetitive inappropriate shoulder movements during bowling, poor throwing technique when fielding. When bowling, batting or fielding repeated throwing using the same arm may result in shoulder overuse, causing some degenerative changes in the rotator cuff, tendinitis and over-stretching or tear of the supraspinatus tendon can be witnessed.\(^20\)

The two most common types of injuries among cricketers were sprain (45%) and strain (30%) compared among wounds, fractures, dislocation and cramps. Similar findings to the present study were found in line with those of Stretch\(^1\), Kumar et al.\(^14\), Das et al.\(^11\), Stretch & Trella.\(^\text{2}\) Training high schools’ cricketers need coaches, parents and clubs who are knowledgeable to strength and flexibility balanced training to produce better performance and fewer injuries/ pain. Noorbhai et al.\(^\text{17}\) emphasised that the chances rate of injury and pain among players can be reduced by initiating more strength and flexibility training.

**Conclusion**

It was noted that prevalence of injuries in high school cricket is high in bowlers than other play positions. This, therefore means that coaches should consider conditioning of players, warm up activities should address nature of injuries and injured part noted, also fitness testing for endurance, agility, power, strength and flexibility need to be introduced in the training program to minimize the rate of injury. **Database for cricket-related musculoskeletal injury of male adolescent cricketers in Zimbabwe is essential for coaches, physicians and physiotherapists to condense the injury rate. Future researchers may consider the following; analysis of player position and injury, improvement of play technique, playtime visa-vie injury prevention and consideration of a specific number of over for specific age groups to reduce overuse and injuries.**

**Limitations of the study**

Cricket playtime and time of research was retrospective. Despite having taught how to report pain and injury, the cricketers may have not reported more than one injury. Data collection was done late after season and was only from the central region out of the four regions.
