The effect of a Pilates exercise programme on perceived functional disability and pain associated with non-specific chronic low back pain

Abstract
Non-specific low back pain (LBP) is a symptom of unknown cause affecting one third of the UK adult population, accounting for more than 15 million lost work days and an estimated annual cost of £12.3 billion. Pilates based exercise is becoming increasingly incorporated in to spinal rehabilitation, yet there is limited evidence on the efficacy of the technique. The aim of this study was to evaluate the effect of a 6–week Pilates based exercise programme on perceived functional disability, pain, local muscular endurance and lumbar range of motion in patients with non-specific chronic low back pain. Participants (n=13) with chronic non-specific LBP (>12-weeks) were recruited to a pre-post intervention trial. All participants were assigned to a 6-week control period. Subsequently, participants undertook one hour of a Pilates based exercise intervention twice per week for 6-weeks. Perceived functional disability and pain were assessed using the Oswestry functional disability questionnaire (ODQ) and visual analogue scale (VAS) respectively. Local muscular endurance (CE) and lumbar range of motion (LF) were assessed using the core endurance test and the fingertip to floor distance (FFD) respectively. Functional disability (ODQ), pain (VAS), local muscular endurance and lumbar flexion (FFD) improved after the intervention period (P<0.05). Improvements in perceived functional disability (ODQ) were associated with an increase in LF (P<0.05) but not VAS or CE (P>0.05). The results of this pre-post intervention trial suggest that Pilates based exercise can be administered safely and is well tolerated by the majority of patients with non-specific chronic LBP.

Keywords: pilates, low back pain, exercise, therapy, functional disability, core stability, core endurance, lumbar flexion

Abbreviations: LBP, low back pain; TrA, transverse abdominis; IO, internal oblique; MF, multifidus; ODQ, oswestry functional disability questionnaire; VAS, visual analogue scale; LSN, lumbar spine neutral; FFD, fingertip to floor distance; CE, core endurance; LF, lumbar flexion

Introduction
Non-specific low back pain (LBP) is a symptom of unknown cause affecting one third of the UK adult population. In 2013 the UK Government reported that back pain was the leading cause of long-term sickness and accounted for more than 15 million lost work days with an estimated annual cost of £12.3 billion. However the therapeutic management of LBP varies widely and the effectiveness associated with many interventions has not been definitively demonstrated. Exercise has been reported as an effective strategy for the management of LBP. However the most suitable method of exercise in the treatment of LBP has been widely debated. Recently Pilates based exercises have been increasingly incorporated into physiotherapy rehabilitation programmes. The Pilates technique focuses on the principles of centring, postural alignment, co-ordination, concentration, breathing, precision and movement sequencing. These principles aim to allow dysfunctional movement to be isolated perfected then integrated back into functional movement and teach control of spinal movement during activities of daily living. The centring principle consists of an isometric contraction of the transverse Abdominis (TrA) and the internal oblique (IO) muscles which contributes to increased antagonist co activation of the deep lumbar muscles viz. multifidus (MF). Several authors have suggested that Pilates based exercise incorporates lumbar stabilisation training within dynamic and functional movement. Chronic LBP can impact on functional activities of daily living. The Oswestry Disability Questionnaire (ODQ) was designed to assess the impact of back pain on activities of daily living and has been shown to be a valid and responsive measure of functional disability. Scores from the ODQ are expressed as percentages and interpreted as, <20% minimal disability, 21-40% moderate disability, 41-60% severe disability, 61-80% crippling back pain, 81-100% bed bound or patients were exaggerating symptoms. A ten percent change in ODQ score is considered the minimum acceptable change to be clinically meaningful. Interlinked with functional disability is the patient’s perception of pain. Pain severity and relief is commonly evaluated using the Visual Analogue Scale (VAS). The VAS consists of a 100mm straight line anchored by 0 (no pain) and 10 (worst pain). The recommended cut offs for the VAS are no pain (0-4mm), mild pain (5-44mm), moderate pain (45-74mm) and severe pain (75-100mm). The VAS is regarded as a valid tool to measure pain severity in chronic pain patients and a reduction of 13mm represents the minimum change in pain to be clinically significant.
The effect of a Pilates exercise programme on perceived functional disability and pain associated with non-specific chronic low back pain

Activities of daily living such as bending down to lift an object from the floor require a combination of strength and range of motion. Impairments in core endurance have been associated with LBP and lower extremity injuries in athletes. The core endurance test is a measure of trunk control and can be used to assess the fatigability of the trunk muscles with moderate to high intra-rater reliability (ICC=0.66-0.96). Akaha et al. reported that deficiencies in trunk flexibility closely reflected self-reported disability in activities of daily living and the fingertip to floor distance (FFD) test measures trunk flexibility and can be used to study lumbar impairment. Pilates based exercise has been suggested to demonstrate positive effects for improved general function and pain reduction with some evidence to support improvements in flexibility and enhanced muscle endurance and as such may offer an alternative cost effective method in the management of LBP. Increasingly therapists in Australia and the United States are using Pilates as an intervention in the management of chronic LBP despite minimal scientific evidence to support the technique. Therefore the aim of this study was to evaluate the effect of a 6-week Pilates based exercise programme on perceived functional disability, pain, local muscular endurance and lumbar range of motion associated with non-specific chronic low back pain.

Methods
Participants and procedures
Fifteen physically active (defined by the UK Government as 150 minutes of moderate intensity activity per week) participants (Female n=10, age 57.4±6.6 years, Male n=5, age 50.4±9.9 years) with non-specific LBP (>12 weeks) were recruited to this study. Exclusion criteria included pregnancy, manual treatment within the previous 3 months, positive straight leg raise test, prior spinal surgery, known lumbar disc hernia, severe osteoporosis and diagnosed inflammatory or malignant disease. Two participants were excluded from the study due to receiving previous spinal surgery. The study was designed as a prospective pre-post intervention trial as it is deemed unethical to deny any participant with LBP access to treatment. Participants undertook a 6-week control period in which they continued their daily and physical activities as normal. Subsequently participants commenced one hour of a supervised (1:4 ratio) Pilates based exercise intervention twice per week for 6-weeks. Each session included a 10-minute warm-up concentrating on movements of the trunk musculature. Participants were taught to find lumbar spine neutral (LSN) as the intermediate position between retroversion and anteverision. Activation and control of the TrA and MF muscles was established with expiration during diaphragmatic breathing in different positions (standing, sitting, supine, prone and four-point kneeling) based on the Pilates technique. The exercise intervention included the following Pilates movements, spine stretch forward, spine twist, single leg stretch, rolling, the hundred, diamond press, side kick and shoulder bridge. Exercise intensity and duration was progressed in accordance with the ACSM guidelines for chronic low back pain.

Perceived functional disability and pain
Perceived functional disability and pain were assessed pre and post control and intervention periods using the ODQ and VAS respectively. Participants were requested to complete the applicable sections of the ODQ and their percentage of functional disability was calculated on the number of questions completed. Levels of perceived pain in the previous 24-hour period were established by participants marking a vertical mark through the 100mm horizontal VAS the distance was measured and recorded in millimetres (mm).

Local muscular endurance and lumbar range of motion
Local muscular endurance was established by conducting a core endurance test in accordance with protocols established by Mc Gill. Participants were instructed to hold a static position for as long as possible the test was terminated when the subject could no longer sustain the position and the time recorded in seconds (s). Lumbar flexion range of motion was assessed using fingertip to floor distance (FFD). Participants were instructed to hold feet hip width apart arms held straight in front with hands together then to slowly bend forward in an attempt to touch the floor. The distance between the tip of the middle finger and the floor was measured and recorded in centimetres (cm).

Pilates based exercise
Participants completed one hour of a supervised (1:4 ratio) Pilates exercise twice per week for 6-weeks. Each session included a 10-minute warm-up concentrating on movements of the trunk musculature. Participants were taught to find lumbar spine neutral (LSN) as the intermediate position between retroversion and anteverision. Activation and control of the TrA and MF muscles was established with expiration during diaphragmatic breathing in different positions (standing, sitting, supine, prone and four-point kneeling) based on the Pilates technique. The exercise intervention included the following Pilates movements, spine stretch forward, spine twist, single leg stretch, rolling, the hundred, diamond press, side kick and shoulder bridge.

Statistical analysis
To assess normality of the data distribution a Shapiro-Wilk test was used. Descriptive statistics are reported as mean±standard deviation and median (Interquartile range). A paired samples t-test was used to analyze differences for both the control and intervention periods from baseline to 6-weeks for core endurance (CE) and lumbar flexion (LF). Where data were not normally distributed a non-parametric related-samples Wilcoxon signed rank test was performed to analyze perceived functional disability (ODQ) and pain (VAS). A Spearman’s rank-order correlation was used to investigate any association between percentage change in LF, VAS, CE and ODQ after the 6-week Pilates intervention. Analyses of data were performed using the statistical

software SPSS 22 for Windows (SPSS Inc, Chicago IL, USA). A statistical significance value of $P<0.05$ was accepted.

**Results**

Participant recruitment, exclusion, participation and withdrawal are presented in Figure 2. Twelve participants (Female $n=7$, age 55.7±6.6 years, Male $n=5$, age 50.4±9.9 years) completed the study and their data was analysed. One participant performed a bout of eccentric exercise (unaccustomed) 24 hours prior to the end of the intervention which led to a 550% increase in pain over and above the range for all participants (-74% to +67%). This data was removed from further analysis. There was no difference in outcome measures after the 6-week control period Table 1. Functional disability (ODQ), pain (VAS), core endurance and lumbar flexion improved after the intervention period ($P<0.05$) Table 2. Mean and individual relative percentage changes in functional disability had a moderate ($r=0.645, P=0.032$) association with improvements in lumbar flexion Table 3. Changes in perceived pain and core endurance were not associated with changes in perception of functional disability ($P>0.05$).

**Discussion**

The results of this pre-post intervention trial suggest that Pilates based exercise can be administered safely and is well tolerated by the majority (11/12) of patients with non-specific chronic LBP. Furthermore mean absolute and relative changes indicated that it may have the potential to promote a clinically meaningful change in perceived functional disability and pain in this patient group. These mean changes are underpinned by 75% of the sample having a reduction (>13mm) in pain post-intervention. Reductions in ODQ and VAS scores followed a similar trend for the majority of participants but it is not known if the reduction in perceived pain led to a reduction in functional disability. Improvements in LF and CE post intervention were observed for 92% and 75% of the sample respectively. Moreover increased LF was moderately associated with a reduction of perceived functional disability.

The results of the present investigation are in accordance with Taylor et al. and Natour et al. who observed improvements in pain and self-reported disability after 6 and 12-week Pilates’ interventions respectively. Importantly our study observed mean decreases of 33% in the ODQ and 15mm in VAS scores which represents a clinically meaningful change. Both Taylor et al. and Natour et al. employed the VAS to measure pain and observed similar decreases of 19mm and 15.9mm. However in contrast to our study Natour et al. measured functional disability using the Roland-Morris Disability Questionnaire which unlike the ODQ requires a response to all questions regardless of patient relevance. We cannot infer causation using the current study design nor did we investigate mechanisms of action associated with...
Pilates exercise although the improvements in functional disability may be suggestive of muscle recruitment (TrA, MF) which enhance static and dynamic posture. In a review of exercise interventions for LBP Searle et al. reported that interventions with an emphasis on isometric contractions of TrA contributed to lumbo-pelvic stability when stability was challenged. Furthermore Rio et al. observed that isometric contractions of the quadriceps femoris induced greater immediate analgesia in patella tendinopathy patients compared to concentric eccentric contractions. This has been suggested to increase the ability to load or perform in the post contraction analgesic phase. However it is unclear whether the benefits of exercise to reduce perceived pain associated with chronic LBP are as a consequence of muscle loading or movement repetition.

Improvements in the perception of functional disability and pain as a result of the Pilates exercise may contribute to improvements in core muscle endurance and range of motion. Richmond suggested that transciends into integrated movement may improve resistance to fatigue of muscles associated with maintaining balance after a postural perturbation. CE improved post-intervention which is in accordance with the work of Natour et al. who purported that Pilates improved core strength because of higher levels of TrA contraction. In addition Kamioka et al. reported that there was strong evidence that in a healthy population Pilates exercise improved flexibility and enhanced muscular endurance in the short term. While our study did not specifically measure TrA contraction Searle et al. noted that isolated training of TrA led to an earlier onset of TrA activation which reflected a more constant activation pattern that is observed in healthy individuals. The increase in CE found in our study could not be attributed solely to TrA and MF contraction as the method of testing recruited both global and local musculature which was not specifically trained in the intervention. This may explain the varied response to changes in CE found in our study. Improvement in LF has a moderate association with a reduction in scores on the ODQ. This is in agreement with the hypothesis that improved perception of total lumbar flexion through FFD may reflect self-reported disability in activities of daily living. However this association must be interpreted cognisant that LF is measured using an objective test, unlike the QOD which relies on patient perception and interpretation of functional disability. The observed improvements in LF could be due to the exercises that were included in our study. Kumar et al. suggested exercises that created a stretch in the lumbar muscles, such as the spine stretch forward, rolling and spine twist performed in our study, could restore mobility which had been disturbed in chronic LBP. In contrast to our study Natour et al. did not find any significant improvements in LF. This may have been due to the disparity in testing procedures used to measure LF as Natour et al. used a sit and reach test which may not have sufficiently represented lumbar spine flexibility and could be influenced by hamstring flexibility.

The current study established the short-term effects of the Pilates exercise on perceived functional disability and pain and objectively measured LF and CE. However the long-term efficacy and maintenance of improvements could not be established and this should be considered for future research.

Conclusion

The present study has provided sufficient trends to justify the use of a Pilates programme for the reduction of perceived functional disability and pain. In addition the Pilates exercise protocol improved core muscle endurance and lumbar flexibility. While it is acknowledged that further investigation is required into the proposed effects of the technique a Pilates based exercise intervention could offer a cost-effective alternative to traditional manual therapy interventions for non-specific chronic LBP.
